Topical application of amphotericin B is highly effective and well tolerated in the treatment of cutaneous and mucocutaneous candidoses. This is also true for inhalation and instillation. Local irritations and allergic reactions may occur in rare cases and are partly due to the galenic formulation.

3.2. Natamycin (Pimaricin)

Natamycin [*7681-93-8*], natural product isolated from culture filtrates of *Streptomyces natalensis* (original isolate from soil of Pietermaritzburg, South Africa) and *Streptomyces chattanoogensis* [208], [209], contains mycosamine as sugar component, like amphotericin B and nystatin. $C_{33}H_{47}NO_{13}$, M_r 665.7, *mp*: does not have an exact melting point and decomposes above 200 °C, colorless substance.

Synonym(s). Pimaricin, antibiotic A 5283, CL 12625, tennecetin.

Solubility. Natamycin is soluble in propylene glycol (20 mg/mL), DMF (50 mg/mL), and *N*-methylpyrrolidone (120 mg/mL); slightly soluble in methanol (2 mg/mL); and practically insoluble in water (0.05 mg/mL). Natamycin is amphoteric, dissolving in dilute acids and bases. However, these solutions are unstable.

Stability. Solutions or suspensions of natamycin are stable for several weeks at pH 5 – 7. The solutions can even be sterilized by heating at 110 °C for 20 min. However, they must be protected from light, which causes rapid decomposition [208], [210].

Synthesis. Fermentative from *Streptomyces* species.

Description. First isolated in 1957 [208], [211], [212].

Formulations. For therapy of human infections: Ointments, powders, creams, lotions, lozenges, dragees, suspensions, and vaginal tablets of different concentration. Also in combination with antibiotics and/or steroids (e.g., neomycine, hydrocortisone).

Trade Names. Deronga (Basotherm), Mycophyt (Gist-Brocades), Myprozine (Lederle), Natacyn (Alcon), Natafucin (Brocades), Pima-Biciron (Basotherm), Pimafucin (Basotherm, Beytout, Byk Procienx, Gist-Brocades), Pimagyn (Doetsch-Grether), Synogil (Basotherm).

Antimycotic Properties. Natamycin is a broad-spectrum polyene antimycotic, MIC values are summarized in Table 7.

Phamacokinetics. After topical application, no systemic absoption was detectable.

Indications. Cutaneous and mucocutaneous candidosis; in some cases, the substance was also successful for therapy of human dermatophytoses [213–215]. In veterinary medicin, natamycin is used for the therapy of dermatophytoses in cows (generally caused by *Trichophyton verrucosum*) and horses (generally caused by *Trichophyton equinum*) [216], [217]. As natamycin also has antibacterial properties, it is also used as a food preservative.

Side Effects. When applied topically, natamycin is highly effective and well tolerated in the treatment of cutaneous and mucocutaneous candidoses. Local irritations and allergic reactions may occur in rare cases and are mostly due to the galenic formulation. Especially in veterinary medicine, phototoxic effects were observed.

3.3. Nystatin A1

Nystatin (A1) [*1400-61-9*], three biologically active components – Nystatin A1, A2, and A3 – have been described. Nystatin A1 is a natural product isolated from culture filtrates of *Streptomyces noursei* [218], *Streptomyces aureus*, and other *Streptomyces* species. Like amphtericin B it is a 38-membered macrocyclic lactone, from which it differs solely in the position of the hydroxyl groups and in the absence of a double bond at C23 [219]. $C_{47}H_{75}NO_{17}$, M_r 926.1, *mp*: does not have a melting point, begins to decompose above 160 °C and decomposes above 250 °C without melting, yellow powder.

Synonym(s). Polyfungin A1.

Solubility. Nystatin A1 is soluble in pyridine, DMSO, DMF, ethylene glycol (8.7 µg/mL), methanol (11 µg/mL), ethanol (1.2 µg/mL), butanol, dioxane, and water (4.0 µg/mL). The substance is hygroscopic [220].

Stability. The substance is amphoteric, but aqueous and alkaline solutions are unstable. Nystatin shows optimum stability in phosphate – citrate buffers at pH 5 – 7. If kept refrigerated, the pure substance can be stored for several months without loss of activity. For stability, see [221].

Synthesis. Fermentative from *Streptomyces* species.

Description. See [222], [223].

Formulations. Tablets, dragées, lozenges, suspensions, drops, ointments, powders, gels, creams, ovulas, and vaginal tablets of different concentrations. There are also formulations available in combination with antibiotics and/or steroids such as tetracycline, neomycin, gramicidin, and cortisone. Dosages are often expressed in IE (100 000 IE = 22.73 mg nystatin A1).

Trade Names. Adiclair (Ardeypharm), Biofanal (Pfleger), Candex (Dome), Candio-Hermal (Hermal, Merck), Canstat (Lederle), Diastatin (Pfizer), Fungicidin (Spofa), Fungireduct (Azupharma), Herniocid (Mayrhofer), Korostatin (Holland-Rantos), Lederlind (Lederle), Lystin (Mekim), Mikostatin (Squibb), Moronal (Heyden, Squibb), Multilind (Bristol-Myers Squibb, Fair), Mycostatin (Bristol-Myers Squibb, Heyden, Sanofi Winthrop, Westwood-Squibb), Mykinac (NMC), Myco-Posterine N (Kade), Mykundex (Jossa), Nadostine (Pan-Well), Nilstat (Lederle), Nyaderm (Taro), Nysert (Norwich Eaton), Nystacid (Farmos Group), Nystaderm (Dermapharm), Nysta-Dome (Dome), Nystan (Squibb), Nystat-Rx (Pharma-Tek), Nystavescent (Squibb), Nystex (Savage), Oranyst (Taro), O-V Statin (Squibb), Restatin (Remedica), Rivostatin (Rivopharm) Stereomycin (Medica).

Antimycotic Properties. Nystatin A1 is a broad-spectrum polyene antimycotic with in vitro activity against pathogenic yeasts, moulds,

dermatophytes, and dimophic fungi. MIC values of nystatin are summarized in Table 12.

Pharmacokinetics. After topical application, no systemic absorption was detectable.

Indications. Nystatin A1 is especially indicated in the therapy of cutaneous and mucocutaneous infections caused by pathogenic yeasts.

Side Effects. When applied topically, nystatin A1 is highly effective and well tolerated in the treatment of cutaneous and mucocutaneous candidoses. Local irritations and allergic reactions may occur in rare cases and are mostly due to the galenic formulation. If topically applicated in the gastrointestinal tract, nausea, vomiting, and diarrhoea are rarely observed.

4. Flucytosine

Flucytosine [*2022-85-7*], 4-amino-5-fluoro-2(1*H*)-pyrimidinone, $C_4H_4FN_3O$, M_r 129.03, *mp* 297 °C (decomp.), colorless crystals.

Synonym(s). Fluorocytosine, 5-Flurocytosine, 5-FC, Ro 2-9915.

Solubility. Flucytosine is readily soluble in water. It is basic and forms salts with acids.

Stability. Pure flucytosine as well as aqueous solutions, both acidic and basic, are stable. The substance should be stored in the dark.

Synthesis. The synthesis begins with *S*-ethylisothioureahydrobromide and ethyl-2-fluoro-3-methoxy-acrylate [224], [225]:

Description. The substance was initially synthesized at Hoffmann-La Roche Pharmaceuticals as an antimetabolite [224], [226–228].

Formulations. Infusion bottles à 0.1, 0.2, and 0.4 g. Capsules à 0.05, 0.1, 0.15, and 0.2 g. 0.5 and 1 % suspensions for oral application, 10 % suspension creams.

Trade Names. Alcoban (Roche), Alcobon (Roche), Ancobon (Roche), Ancotil (Edward Keller, Hoffmann-La Roche, Roche), Cocol (Horita, Tobishi).

Mechanism of Action. The mechanism of action of flucytosine is based on the incorporation of 5-fluorouracil, which is relatively selectively formed in fungal cells by deamination of flucytosine by the fungal cytosine-desaminase, into the messenger RNA and ribosomal RNA of the fungal cell. Fungal RNA containing 5-fluorouracil-riboside increasingly inhibits fungal protein biosynthesis [231–234].

Antimycotic Properties. Flucytosine has a narrow in vitro antimycotic activity spectrum that includes yeasts, *Cryptococcus neoformans*, as well as some *Aspergillus* strains and some chromomycetes. The activity spectrum and MIC values of flucytosine are summarized in Table 9 [231], [232]. Because the antimycotic action of flucytosine is antagonized by purines, pyrimidines, peptides, and some amino acids in vitro, only media free from these antagonists, e.g., yeast – nitrogen base medium containing dextrose, can be used for in vitro testing. Of the

fungus strains affected by flucytosine, more than 10 % can be expected to show primary resistance. The development of secondary resistance by sensitive fungi during treatment also occurs, especially in cases of underdosage or prolonged treatment [232], [234]. In vitro fungicidal effects can be obtained with > 10 times the MIC and a contact time of > 150 h.

Pharmacokinetics. Flucytosine can be administered orally, parenterally, and topically. After oral administration, the drug is absorbed rapidly and almost completely in the intestine (80 – 90 %) [235]. Average serum concentrations of 30 – 60 µg/mL are normally reached with a single oral dose of 35 mg/kg. In patients with normal kidney function, optimal continuous serum levels between 25 and 100 mg/L are achieved with a dose of 50 mg/kg every 6 h [236]. Flucytosine penetrates readily into the tissues, body fluids, and cerebrospinal fluid (CSF) [237]. The CSF level reaches approximately 70 – 80 % of blood levels [236]. The plasma protein binding of flucytosine is low (ca. 4 %) [238]. More than 90 % of the dose is eliminated via the kidneys in unchanged form. The elimination half-life is 3 – 6 h. In patients with severely impaired kidney function, the elimination half-life can rise to 4 d. In patients with restricted renal function, the daily dose of flucytosine therefore must be adjusted according to creatinine elimination. The compound can be readily eliminated by hemodialysis [231–233]. A small amount of flucytosine is metabolized to 5-fluorouracil, e.g., by the bacterial flora of the gut, which seems to be a reason for the hematotoxicity of flucytos e [239], [240].

Table 9. MIC values for flucytosine

Fungus	MIC range, µg/mL
Candida albicans	0.1 – 10 (> 100)
Candida tropicalis	0.1 – 100
Candida parapsilosis	0.1 – 0.5
Candida pseudotropicalis	0.1
Candida krusei	0.5 – 1
Candida (Torulopsis) glabrata	0.1 – 1
Cryptococcus neoformans	0.5 – 4 (16)
Aspergillus fumigatus	0.5 – 10
Aspergillus niger	0.5 – 1
Aspergillus flavus	1
Aspergillus nidulans	100
Phialophora species	1 – 10
Cladosporium species	1 – 10

Indications. Flucytosine has proved very effective in the treatment of *Candida* fungemia and systemic candidoses (but not mucocutaneous candidiasis) in combination with amphotericin B. Also, *Cryptococcus* infections, including *Cryptococcus neoformans* meningoencephalitis in immunocompromized patients (e.g., AIDS patients), can be treated with flucytosine in combination with amphotericin B (and in the case of *Cryptococcus neoformans* associated infections, additionally fluconazole). Further, flucytosine is indicated in the therapy of chromomycoses [241]. There can also be some activity of flucytosine in disseminated aspergilloses. Because of the rapid development of resistance, the substance should only be given in combination with other antimycotic agents, mostly amphotericin B [242].

Side Effects. Flucytosine is normally well tolerated provided dosage instructions are observed and precautionary measures are taken [232]. The following side effects have been observed during treatment with flucytosine: *Blood/spleen.* Neutropenia, leukopenia, thrombopenia [243].

GIT. Nausea, vomiting, and diarrhoea were observed in rare cases [243].

Liver. Liver malfunctions with reversible hepatomegalia and increase in serum transaminases; an extensive liver cell necrosis was reported after flucytosine therapy in two patients [243].

Skin. Allergic skin reactions were observed under therapy. Changes in blood counts can have serious consequences. Blood counts and liver function should therefore be checked regularly during therapy. Hematotoxic side effects were especially observed if serum levels exceeded 100 mg/L. Flucytosine can prolong engraftment in bone marrow transplantation patients.

5. Griseofulvin

Griseofulvin [*126-07-8*], 7-chloro-4,6-trimethoxy-6′-methylspiro[benzofuran-2(3*H*),1′-[2]cyclohexene]-3,4′-dione, $C_{17}H_{17}ClO_6$, M_r 352.8, *mp* 222 °C, colorless crystals.

Synonym(s). Amudane, Curling Factor.

Solubility. Griseofulvin is soluble in methanol (2.5 g/mL), ethanol (1.5 g/mL), ether, and glacial acetic acid; quite soluble in DMF (150 mg/mL); slightly soluble in chloroform (25 mg/mL), ethyl acetate, acetone (33 mg/mL), and toluene; and insoluble in petroleum ether. The solubility in water is 40 µg/mL.

Stability. Griseofulvin is stable under normal storage conditions.

Synthesis. Griseofulvin is mostly produced by fermentation with strains of *Penicillium patulum*. After the first total synthesis in 1960 [244], other processes were published, but none of them has acquired industrial significance up to now.

Description. Griseofulvin was isolated from culture broths of *Penicillium griseofulvum* in 1938 and later also found in culture filtrates of *Penicillium nigricans* (= *P. janczewskii*), *P. patulum*, and other *Penicillium* species. The structure was determined in 1952. Griseofulvin was first used in plant protection and was introduced to medicine as an antimycotic in 1958 [245].

Formulations. Tablets à 125 and 500 mg. 5 % cream formulations.

Trade Names. B-GF (Biokema), Delmofulvina (Coli), Fulcin (ICI, Mason, Zeneca), Fulcin S (ICI), Fulvicin (Schering), Fulvicina (Interpharma), Fulvicin P/G (Schering-Plough), Fungivin (Nycomed), Gefulvine (Dif-Dogu), Greosin (Glaxo), Gricin (Arzneimittelwerke Dresden), Grifulin (Teva), Grifulvin V (McNeil, Ortho), Grisactin (Ayerst, Wyeth), Griséfuline (Sanofi Winthrop), Griseo (Ayerst), Griseoderm (Trinity), Griseomed (Waldheim), Griseostatin (Mason, Schering Corp.), Griseo von ct (ct-Arzneimittel), Grisfulvin (Protea), Grisol (Gebro), Grisovin (Glaxo), Grisovina Fp (Glaxo, Teofarma), Grisovin-FP (Glaxo), Grivate (Fujisawa), Grysio (Ayerst), Lamoryl (Leo, Lövens), Likuden (Hoechst), Norofulvin (Norbrook), Polygris (Schering Corp.), Sulvina (Dibios), Ultragris (Sidmak).

Mechanism of Action. In addition to the inhibition of protein synthesis resulting from the interference of griseofulvin with guanine during RNA synthesis, there may also be a specific inhibition of chitin synthesis. Chitin is an essential cell-wall constituent in dermatophytes. Inhibition of its synthesis would explain the characteristic morphological changes in the hyphae, called curling, that occur in dermatophytes in the presence of griseofulvine [231], [232], [246].

Antimycotic Properties. Griseofulvin has a narrow spectrum of antimycotic activity, including only dermatophytes. *Trichophyton* and *Microsporum* species and *Epidermophyton floccosum* are inhibited by concentrations of 0.1 – 0.5 µg/mL. The in vitro effect of griseofulvin depends primarily on the test system used and is confined to proliferating hyphae. Griseofulvin is fungistatic. Purines and pyrimidines are antagonistic in vitro [232], [247]. Acquired in vitro resistance towards griseofulvin develops gradually following a number of fungal passages [248], [249]. However, increases in resistance during therapy are rarely observed, even during long-term treatment. Although dermatophyte variants showing primary resistance have been described, they are very rare [250]. MIC values for griseofulvin are summarized in Table 10 [14].

Table 10. MIC values for griseofulvine

Fungus	No. isolates tested	MIC range µg/mL
Epidermophyton floccosum	6	3 – > 5
Microsporum canis	19	0.1 – > 18
Microsporum gypseum	6	0.5 – 3.13
Trichophyton mentagrophytes	57	0.1 – > 30
Trichophyton rubrum	558	0.1 – > 30
Trichophyton schoenleinii	170	0.1 – 25
Trichophyton tonsurans	25	0.1 – > 18
Trichophyton violaceum	345	0.1 – 21

Pharmacokinetics. The degree of absorption of orally administered griseofulvin varies from individual to individual from 25 to 75 % of the administered dose. The absorption is strongly dependent on the degree of micronization of the drug, a high fat content in the food also increases absorption. After the administration of a single dose of 0.25 – 0.5 g, serum concentrations reach 0.6 to 1.5 µg/mL. The serum half-life is about 20 h [231], [232], [251]. Griseofulvin accumulates during keratinization in human epidermis cells, hair, and nails. In the course of long-term griseofulvin treatment, concentrations up to 25 µg/g can be detected in the stratum corneum of the skin [232]. Griseofulvin concentrations of 0.2 to 0.3 µg/mL are found in the sweat [252]. Further, the substance shows high concentrations in liver, body fat, and muscles. Griseofulvin is metabolized in the liver and is mostly eliminated by the kidneys in a metabolized, inactive form. Up to 75 % of the quantity absorbed is excreted in the urine as inactive 6-demethylgriseofulvin. The concentration of unchanged griseofulvin in the urine is 1 – 2 µg/mL, corresponding to approximately 1 % of the dose [232], [253]. Elimination occurs biphasically with a terminal elimination half-life of 10 – 40 h [254].

Indications. The indications for griseofulvin are dermatophytoses and onychomycoses which do not respond to topical therapy. The optimal daily dose is 5 – 10 mg/kg body weight. The duration of treatment ranges from 3 to 5 weeks for dermatophytoses of the trunk and extremities, and from 5 to 10 weeks for infections of palms, soles, and scalp, but is more than 6 months and even up to 18 months for onychomycoses [231], [232]. Additional topical therapy increases the cure rate and reduces duration of treatment. Due to better tolerability and efficacy, newer antimycotic compounds such as azole antimycotics and allylamines have mostly replaced griseofulvin in the therapy of dermatomycoses and onychomycoses. Griseofulvin is inactive in mycoses caused by fungi other than dermatophytes.

Side Effects. *CNS.* Headache, depression, dizziness, sleeplessness.

Nerves. Paresthesia and neuropathia [255].

GIT. Dryness of the mouth, changes in taste, and other unspecific gastrointestinal disorders.

Skin. Minor allergic skin reactions, Lyell syndrome [256], erythema multiforme, exfoliative dermatitis, angioedema, photosensitization.

Occasionally, reversible hematopathies, proteinuria, and, especially in case of previous hepatopathy, increases in the liver enzyme values in the blood may be observed. A carcinogenic and embryotoxic potential of griseofulvin was observed in laboratory animals such as rats.

6. Ciclopirox

Ciclopirox [*29342-05-0*], 6-cyclohexyl-1-hydroxy-4-methyl-2(1*H*)-pyridinone, $C_{12}H_{17}NO_2$, M_r 207.27, *mp* 144 °C, colorless crystals.

Ciclopirox olamine [*41621-49-2*], 6-cyclohexyl-1-hydroxy-4-methyl-2(1*H*)-pyridinone olamine, $C_{14}H_{24}N_2O_3$, M_r 268.4, *mp* 143 °C, colorless crystals.

Synonym(s). HOE 296b (free base); Ciclopirox ethanolamine, Hoe 296 (olamine salt).

Stability. The substance is stable under normal storage conditions.

Synthesis. Base **9** is produced by heating 4-methyl-6-cyclohexyl-2-pyrone (**8**) [257] for 8 h at 80 °C with hdroxylamine hydrochloride and 2-aminopyridine [258] or from 5-cyclohexyl-3-methyl-5-oxopentenoate (**10**) [258] by reaction with hydroxylamine hydrochloride via the oxime **11**, followed by cyclization. The final step is to form the salt with ethanolamine.

Description. The substance was first synthesized by Hoechst Pharmaceuticals in 1973 [258–262].

Formulations. 1 % solutions, ointments, and cream preparations.

Trade Names (Ciclopirox). Nagel Batrafen (Casella-Riedel).

Trade Names (Ciclopiroxolamine). Batrafen (Casella-Riedel, Hoechst, Knoll), Brumixol (Bruschettini), Ciclochem (Novag), Dafnegin (Poli), Fungiderm (Heilmittelwerke Wien), Fungowas (Wassermann), Loporox (Hoechst-Roussel), Miclast (Ellem), Micomicen (Vita), Micoxolamin (Delalande), (Sinbio), Obytin (Hoechst, Jugoremedija).

Mechanism of Action. Ciclopirox is a substituted pyridione derivative. Experiments show that the mechanism of action involves a disruption of transport mechanisms into the cell plasma [263], [264], especially the uptake of leucine [265]. Further, the uptake of other amino acids such as phenylalanine and lysine, as well as the uptake of potassium and phosphate ions is impaired. This all probably involves a change in membrane permeability, as reported for some other antimycotics, although ciclopirox does not show lytic activity [263], [264]. Consecutively, the substance significantly reduces fungal growth rates [266].

Antimycotic Properties. Ciclopirox has a broad in vitro antifungal activity spectrum, including dermatophytes, yeasts, and moulds. The most important fungi within the activity spectrum of ciclopirox and the corresponding MIC values are listed in Table 11 [263], [264], [267]. Ciclopirox is primarily fungistatic, but if the contact time is long enough and the concentration exceeds 20 µg/mL, it exerts a fungicidal effect on yeasts and dermatophytes [264]. In vitro, the effect is limited to proliferating fungi and is greatly dependent on the nutrient medium.

Table 11. MIC values for ciclopirox olamine

Species	MIC range, µg/mL
Dermatophytes	0.5 – 5
Candida species	0.5 – 5
Moulds	0.5 – 30

Pharmacokinetics. Ciclopirox penetrates rapidly into and through the skin and nail keratin. After dermal application of a 1 % cream formulation, about 1.3 % of the dose is absorbed. Serum levels range around 10 µg/L after application of a dose of 37 mg of ciclopirox [268]. After vaginal administration, 15 – 20 % of the dose is absorbed [269]. Ciclopirox penetrates well into the skin and nail matrix. Absorbed ciclopirox is mainly eliminated by the kidneys; 1.1 – 1.7 % of the topical dose is eliminated in the urine within four days. Only a fraction thereof is unaltered ciclopirox. Approximately 96 % of the absorbed drug is bound to human serum proteins [270].

Indications. Ciclopirox is indicated for the topical treatment of dermatophytoses and vaginal infections caused by *Candida* species [271].

Side Effects. Topically applied, ciclopirox is well tolerated. The incidence of local irritations such as itching and burning sensations range between 1 and 4 % and are often due to the galenic formulation.

7. Thiocarbamates

Thiocarbamates are inhibitors of fungal squalene epoxidase (see also Chap. 8). By this mechanism, tolciclate and tolnaftate inhibit biosynthesis of fungal ergosterol [272].

7.1. Tolciclate

Tolciclate [*50838-36-3*], methyl (3-methlphenyl)carbamothioic acid *O*-(1,2,3,4-tetrahydro-1,4-methanonaphtalen-6-yl) ester, $C_{20}H_{21}NOS$, M_r 323.46, *mp* 120 – 121 °C, white crystals from ethanol – diethylether.

Synonym(s). KC 9147.

Solubility. The substance shows high liposolubility. Soluble in *n*-hexane (15 mg/mL) and *n*-octanol (24 mg/mL).

Stability. The substance is stable under normal storage conditions, but should be protected from light.

Synthesis. [273]:

Description. Tolciclate was first synthesized at Carlo Erba Pharmaceuticals [274], [275].

Formulations. 1 % solutions, ointments, and cream formulations.

Trade Names. Fungifos (Basotherm), Kilmicen (Carlo Erba), Tolmicen (Carlo Erba, Wing Yee), Tolmicol (Carlo Erba).

Antimycotic Properties. In vitro, tolciclate has a narrow activity spectrum with good efficacy only towards dermatophytes. Isolates of susceptible species showing primary resistance or developing secondary resistance are rarely observed.

Indications. The indications for tolciclate are defined by its narrow spectrum and limited to the treatment of dermatophytoses. Because of inadequate penetration into the nail keratin, it is unlikely to be effective for the treatment of onychomycoses. On average, the efficacy of tolciclate in topical therapy of dermatomycoses is lower than that of most other antimycotics for topical treatment.

Side Effects. Tolciclate is well tolerated on the skin.

7.2. Tolnaftate

Tolnaftate [*2398-96-1*], (3-methylphenyl)carbamothioic acid *O*-2-naphthalenylmethylester, $C_{19}H_{17}NOS$, M_r 307.4, *mp* 110.5 – 111.5 °C, colorless crystals.

Synonym(s). Naphthiomate-T.

Solubility. The substance shows a good solubility in ethanol, ether, and glacial acetic acid; is quite soluble in DMF, chloroform, dichloromethane, and benzene; and practically insoluble in water.

Stability. Tolnaftate is stable under normal storage conditions, but schould be protected from light.

Synthesis. Tolnaftate is synthesized from β-naphthol, thiophosgene, and *N*-methl-*m*-tolulidine by the following pathway [276]. Another route, which does not use thiophosgene, has been described [277].

Description. Tolnaftate was first synthesized by Japan Soda and first described as a topical antimycotic in 1962 [278–281].

Formulations. 1 % solutions, ointments, and cream preparations.

Trade Names. Aftate (JDH, Plough), Alber-T (Hing Yip), Chinofungin (Chinoin), Chlorisept (Chinosol), Ezon-T (Yamanouchi), Focusan (Lundbeck), Footwork (Lederle), Hi-Alarzin (Hing Yip, Yamanouchi), Mikoderm (Akdeniz), NP-27 (Thompson), Pedesal (Krka), Pediderm (Nelson), Pedimycose (Scholl), Pitrex (Taro), Separin (Sumitomo), Sorgoa (Scheurich), Sporiderm (Cétrane), Sporiline (Schering-Plough), Tinacidin (Schering Corp.), Tinactin (Schering-Plough), Tinatox (Brenner), Tinavet (Schering), Tineafax (Wellcome), Ting (Fisons), Tonoftal (Schering), Zeasorb-AF (Stiefel).

Antimycotic Properties. In vitro, tolnaftate has a narrow activity spectrum with fungistatic effect on towards dermatophytes and a few moulds such as some isolates of selected *Aspergillus* species. The MIC values range between 0.1 and 3 µg/mL for susceptible fungi. Isolates of susceptible species showing primary resistance or developing secondary resistance are rarely observed. Tolnaftate is almost ineffective against yeasts and moulds.

Pharmacokinetics. Tolnaftate combines good penetration into the stratus corneum of the skin with poor penetration into nail keratin.

Indications. The indications for tolnaftate are defined by its narrow spectrum and limited to the treatment of dermatophytoses. Tolnaftate is effective when topically administered several times daily over a period of several weeks [231], [232]. Because of its inadequate penetration into nail keratin, tolnaftate is unlikely to be effective for the treatment of onychomycoses. On the average, the efficacy of tolnaftate in topical therapy of dermatomycoses is lower than that of most other antimycotics for topical treatment [282].

Side Effects. Tolnaftate is well tolerated on the skin. Erythemas and allergic reactions are very rare and might also be due to the galenic formulation. No other side effects are known [232], [283].

8. Allylamines

The allylamines are inhibitors of the enzyme squalene epoxidase. This results in an accumulation of squalene, which exhibits lethal effects towards the fungal organism at high concentrations. Thereby, the inhibition of squalene epoxidase blocks ergosterol biosynthesis in the fungal cell [284]. The essential portion of the allylamine molecule is the conjugated enzyme group with a *trans* configuration in the side chain [285]. The enzyme squalene epoxidase is not linked to the cytochrome P450 complex.

8.1. Naftifine

Naftifine [*65472-88-0*], (*E*)-*N*-Methyl-*N*-(3-phenyl-2-propenyl)-1-naphthalenemethenamine, $C_{21}H_{21}N$, M_r 287.40, *bp* 162 – 167 °C, colorless, viscous oil.

Naftifine hydrochloride [*65473-14-5*], $C_{21}H_{22}ClN$, M_r 323.9, *mp* 177 °C, crystals from propanol.

Synthesis. [286], [287]:

Description. See [288–290].

Formulations. 1 % creams, ointments, gels, and solutions.

Trade Names (Naftifine Hydrochloride). Exoderil (Allergan, Novartis, Rentschler, Schering), Fotimin (KRKA), Nafteryl (Schering), Naftin (Allergan).

Antimycotic Properties. Naftifine is fungicidal against dermatophytes such as *Epidermophyton floccosum, Trichophyton* and *Microsporum* species. Against pathogenic yeasts such as *Candida* species and moulds, it shows only an intermediate fungistatic activity in vitro [291], [292].

Pharmacokinetics. Naftifine penetrates well into the stratum corneum of the skin; 2 – 4 % of the topically administered dose were absorbed after administration of a 1 % gel preperation. After occlusion, an absorption of 6 % of the administered dose was observed [293].

Indications. Naftifine is primarily indicated in the therapy of superficial dermatomycoses [294–296]. It also shows some clinical efficacy in superficial infections caused by yeasts and moulds.

Side Effects. Naftifine is well tolerated although rare cases of local skin irritations and contact dermatitis have been found, which might also be due the galenic formulation [293].

8.2. Terbinafine

Terbinafine [*91161-71-6*], (*E*)-*N*-(6,6-dimethyl-2-hepten-4-ynyl)-*N*-methyl-1-naphthalenemethanamine, $C_{21}H_{25}N$, M_r 291.44, colorless crystals.

Terbinafine hydrochloride [*78628-80-4*], $C_{21}H_{26}ClN$, M_r 327.90, *mp* 195 – 198 °C, colorless crystals from 2-propanol diethyl ether, change in crystal structure begins at 150 °C.

Synonym(s). SF 83627, SF 83-627 (both hydrochloride).

Solubility. Terbinafine is a highly lipophilic substance.

Stability. The substance is stable under normal storage conditions.

Synthesis. [297] (see top of next page):

Description. The substance was first synthesized at Sandoz Pharmaceuticals [298].

Formulations. 1 % cream and ointment preparations, and tablets à 250 mg.

Trade Names (Terbinafine). Lamisil (Edward Keller).

Trade Names (Terbinafine Hydrochloride). Lamisil (Sanabo, Sandoz-Wander).

Antimcotic Properties. Terbinafine shows a good and mostly fungicidal in vitro antimycotic activity against dermatophytes such as *Epidermophyton floccosum, Trichophyton,* and *Microsporum* species. The substance also shows a high but often fungistatic in vitro activity against isolates of various *Aspergillus* species. The activity against pathogenic yeasts is quite variable. Many isolates of *Cryptococcus neoformans* and *Candidia parapsilosis* show an in vitro sensitivity towards terbinafine, although isolates of *Candida albicans, Candida (Torulopsis) glabrata,* and *Candida tropicalis* are mostly resistant or have rather high MIC levels [299].

Pharmakocinetics. Terbinafine is well absorbed from the gastrointestinal tract with a bioavailability of 70 – 80 %. Peak plasma concentrations of 0.97 µg/mL were observed following a single oral dose of 250 mg within 2 h

Terbafin hydrochloride (Synthesis 1):

Terbafin hydrochloride (Synthesis 2):

of administration. Steady state concentrations are reached within two weeks of therapy [300]. The substance is highly bound to plasma proteins. After oral administration, terbinafine distributes well into tissues, including skin, the nail plate, sweat, sebum, and hair. Terbinafine is metabolized in the liver to inactive metabolites which are excreted in the urine. Elimination occurs biphasically. Plasma elimination half-lifes of 11 – 17 h have been reported, as has a slower elimination half-life of 90 – 100 h [301]. After topical administration, the lipophilic substance shows a good penetration into the skin and nail matrix and is hardly absorbed (< 5 % of the administered dose) [302].

Indications. Oral and topical treatment of dermatophytoses and onychomycoses [303]. The substance also shows activity in the topical treatment of pityriasis versicolor and cutanous candidiasis. 250 mg of terbinafine are given once daily by mouth for 2 to 4 weeks for therapy of tinea cruris and tinea corporis. Especially for tinea pedis, treatment may have to be continued for up to 6 weeks [292].

Side Effects. The following side effects were observed after oral administration:

CNS. Headache.

GIT. Nausea, diarrhoea, anorexia, mild abdominal pain (5 %) [301].

Arthralgia, myalgia, and skin reactions such as rush and urticaria rarely occur. Severe

skin reactions including erythema multiforme (1:100,000), Stevens – Johnson syndrome and Lyell syndrome have occurred occasionally. Loss or disturbance of taste, which is mostly reversible [304], [305], and liver disfunction have been observed [306]. After topical administration, the substance is well tolerated, although side effects such as skin irritations (e.g., itching and burning sensations) and allergic reaction may occur, which may also often be due to the galenic formulation.

9. Amorolfine

Amorolfine [*78613-35-1*], (±)-*cis*-2,6-dimethyl-4-[2-methyl-3(*p-tert*-pentylphenyl)propyl]morpholine, $C_{21}H_{35}NO$, M_r 317.60, *bp* 134 °C.

Amorolfine hydrochloride [*78613-38-4*], $C_{21}H_{36}ClNO$, M_r 354.06.

Synonym(s). Ro 14-4767/000 (free base); Ro 14-4767/002 (hydrochloride).

Description. The substance was first synthesized at Roche Pharmaceuticals [307], [308].

Formulations. 0.25 % cream preparations, 5 % nail lacquers, 50 mg vaginal tablets.

Trade Names (Amorolfine Hydrochloride). Loceryl (Roche, Sauter), Locéryl (Roche).

Mechanism of Action. Amorolfine is a morpholine derivative and selectively inhibits Δ^{14}-reduction and Δ^{8}-Δ^{7}-isomerase, which are required for Δ^{14}-reductase and Δ^{8}-Δ^{7}-isomerization, following C14 demethylation of lanosterol or 24-methlenedihydrolanosterol in the ergosterol biosnthesis pathway of the fungal cell [309].

Antimycotic Properties. Amorolfine is a broad-spectrum antimycotic [310] with in vitro activity against dermatophytes, pathogenic *Candida* species, and a variety of pathogenic dimophic fungi such as *Blastomyces dermatitidis, Histoplasma capsulatum*, and *Sporothrix schenckii*. The substance also shows some activity against various isolates of *Aspergillus* species.

Pharmacokinetics. Amorolfine is not absorbed after topical administration on normal skin. After application of a single vaginal tablet containing 50 mg of amorolfine, plasma concentrations between 27 and 83 ng/mL were observed [311].

Indications. For the treatment of skin infections, a 0.25 % cream preparation is applied once daily until clinical cure is achieved and then for a further 3 – 5 d [312]. For the treatment of nail mycoses caused by dermatophytes, yeasts, and moulds, a lacquer preparation containing 5 % amorolfine is painted onto the affected nail once or twice a week until the nail has regenerated. Treatment of onychomycoses normally needs to be continued for up to 1 year. Amorolfine is also active in the treatment of vaginal candidiasis.

Side Effects. Skin irritations, such as erythema, pruritus, or a burning sensation, rarely occur.

10. Unspecific Topical Antimycotics

Other unspecific antimycotics for topical use are listed in Table 12. These somewhat "historical" substances are of minor importance in clinical use nowadays, as highly effective and safe specific substances have become available.

11. Recent Developments and Outlook

The antimycotic market is clearly dominated by azoles, especially for the treatment of systemic mycoses. The latter market is led by fluconazole and itraconazole. Improved azoles are in clinical development (mostly phase I and II); pradimicins, aureobasidins, echinocandins, and pneumocandins for the treatment of systemic mycoses. The new azoles are reported to have

Table 12. Other unspecified topical antimycotics

Generic name	Structural formula	Activity spectrum
Quaternary ammonium compounds		
Benzalkonium chloride [*8001-54-5*]		Dermatophytes, yeasts, moulds
Domiphen bromide [*13900-14-6*]		Dermatophytes, yeasts, moulds
Dibromosalane [*87-12-7*]		Dermatophytes, yeasts, gram-positive bacteria
Chloroquinaldol [*72-80-0*]		Dermatophytes, yeasts
Dichlorophene [*97-23-4*]		Dermatophytes, yeasts
Hexachlorophene [*70-30-4*]		Dermatophytes, yeasts, gram-positive bacteria
Dibenzthione [*350-12-9*]		Dermatophytes, yeasts
Chlormidazole [*3689-76-7*]		Dermatophytes, yeasts
Mercury compounds		
Merbromin (Mercurochrome) [*129-16-8*]		Dermatophytes, yeasts, bacteria
Thimerosal [*54-64-8*]		Dermatophytes, yeasts, bacteria
Triphenylmethane dyes		
Fuchsin (basic violet) [*632-99-5*]		Dermatophytes, yeasts
Undecylenic acid [*112-38-9*]	$CH_2=CH(CH_2)_8COOH$	Dermatophytes, yeasts

activity against fluconazole-resistant strains and species as well as a broader spectrum of antifungal activity. Except the azoles, all other reported compounds habe a relatively low bioavailability and/or tolerability on the average which may limit their use to therapy of life threatening infections within the hospital segment. Production costs of all these compounds seem to be rather high as compared, e.g., to fluconazole.

Significant increase in research activities in antifungals for systemic application has been observed within the last few years in many pharmaceutical companies and institutes worldwide due to the high medical need and the fast growing market. Therefore, the chances for the development of new antifungal agents with new chemical structures and new mechanisms of action are improving.

1. Introduction

Organic matter has a strong tendency to react with oxygen and oxidize. This is true for most commercial organic materials, e.g., plastics, elastomers, fibers, fuels, lubricants, and foods. It is also true for humans, if aging is considered to be, at least in part, an oxidation process.

In 1861, A. W. VON HOFMANN first made the connection between oxygen and the deterioration of polymer properties in his studies on the aging of gutta-percha [1]. The concept of antioxidants and the discovery that small amounts of reducing agents could protect materials susceptible to oxidation were attributed to S. L. BIGELOW (1898) for sodium sulfite solution [2]; to P. SISLEY (1903 and 1904) for the stabilization of dyed silk to oxidation by hydroquinone (among other compounds); to A. LUMIÈRE, L. LUMIÈRE, and A. SEYEWETZ (1905) for the protection of photographic developers (these authors first used the term antioxidant); and to CH. MOUREU and CH. DUFRAISSE (1920) for the protection of acrolein.

Virtually all polymers that have become commercial products since these early years are dependent on stabilizing additives, antioxidants, which permit the polymers to withstand the oxidative stresses of processing and fabrication and to be used in so many different ways.

Oxidation of organic materials takes place by a number of processes:

autooxidation
biooxidation
combustion
photooxidation

The ultimate result of these processes is the conversion of carbon and hydrogen in organic compounds to carbon dioxide and water, with the accompanying release of large amounts of energy for each mole of carbon dioxide and water formed. In the autooxidation of commercial organic materials, oxidation to carbon dioxide and water is seldom complete.

This article primarily describes the *autooxidation* of organic materials and its prevention by antioxidants, with emphasis on the autooxidation of commercially produced polymers. *Biooxidation* and *combustion* are important processes but are not covered here. *Photooxidation* is discussed only briefly. Although conventional antioxidants, such as hindered phenols, thio-

10.1002/14356007.a03_091

synergists, and phosphites, also are moderate stabilizers of organic materials against photo-oxidation, other, more effective additives, especially ultraviolet absorbers, hindered amines, and nickel chelates, are required to give adequate light stability.

Antioxidants, also called inhibitors (of oxidation), are organic compounds that are added to oxidizable organic materials to retard auto-oxidation and, in general, to prolong the useful life of the substrates. Relatively few chemical classes are effective as antioxidants. Those in common use are hindered phenols, secondary aromatic amines, certain sulfide esters, trivalent phosphorus compounds, hindered amines, metal dithiocarbamates, and metal dithiophosphates.

Another class of stabilizers, the metal deactivators, reduces markedly the rate of oxidation of polyolefin insulation on copper conductors.

Some antioxidants are capable of functioning alone as *primary stabilizers.* These are the hindered phenols, aromatic amines, metal dithiocarbamates and phosphates, and hindered amines. The phosphites and sulfide esters are *secondary stabilizers* and are used most commonly in conjunction with primary stabilizers. Stabilizer practices are discussed Chapter 5.

Many of the secondary aromatic amines derived from *p*-phenylenediamine are active as both antioxidants and antiozonants. *Antiozonants* are added to unsaturated elastomers to reduce the rate of ozone cracking that arises from the reaction of ozone with carbon – carbon double bonds in the polymer. This reaction ultimately leads to chain cleavage and to cracking of the elastomer when sufficient numbers of bonds are broken.

2. Oxidation

Oxygen is a key factor in oxidation. In the ground state, it exists as a biradical (**1**) and reacts readily with carbon free radicals, even at ambient temperatures, to yield *peroxy radicals*

$$\underset{\mathbf{1}}{\mathrm{RCH_2\cdot + \cdot O-O\cdot}} \longrightarrow \mathrm{RCH_2OO\cdot}$$

The reaction of carbon free radicals with oxygen has such a low-activation energy that it is the preferred pathway when not limited by oxygen diffusion. The resulting peroxy radicals abstract hydrogen from the substrate, generating another carbon free radical and *a hydroperoxide*:

$$\mathrm{RCH_2OO\cdot + RH} \longrightarrow \mathrm{CH_2OOH + R\cdot}$$

This reaction has severe consequences for the organic material because: (1) it is a chain reaction that has a significant length and can cause extensive localized oxidation before termination; (2) the hydroperoxide can yield *radical initiators* of oxidation by unimolecular and bimolecular processes:

$$\mathrm{RCH_2OOH} \longrightarrow \mathrm{RCH_2O\cdot + HO\cdot}$$

$$\mathrm{2\,RCH_2OOH} \longrightarrow \mathrm{RCH_2OO\cdot + RCH_2O\cdot + H_2O}$$

Unless these radical reactions are inhibited with antioxidants, the organic substance can quickly deteriorate. The physical properties and appearance of polymers and elastomers are reduced, fuels and lubricants sour, and foods lose their flavor and become rancid.

Ions of certain *metals,* e.g., copper, iron, and cobalt, which can exist in two oxidation states, act as catalysts to decompose hydroperoxides:

$$\begin{array}{l} \mathrm{M^{n+} + ROOH} \longrightarrow \mathrm{M^{(n+1)+} + RO\cdot + OH^-} \\ \mathrm{M^{(n+1)+} + ROOH} \longrightarrow \mathrm{M^{n+} + ROO\cdot + H^+} \\ \hline \mathrm{2\,ROOH} \longrightarrow \mathrm{RO\cdot + ROO\cdot + H_2O} \end{array}$$

Hydroperoxides are also susceptible to *photolytic cleavage* by near ultraviolet light (< 400 nm but particularly ca. 300 nm):

$$\mathrm{RCH_2OOH} \xrightarrow{h\nu} \mathrm{RCH_2O\cdot + HO\cdot}$$

Temperature plays a key role in the rate of oxidation of organic materials. Most materials are subjected, however briefly during some stage, to relatively high temperatures; in these intervals significant oxidation can occur and significant amounts of oxidation initiators can be formed. Commercial polymers (thermoplastics, elastomers, synthetic fibers) are dried, processed, and fabricated at elevated temperatures; lubricants are employed at elevated temperatures; foods are cooked at high temperatures. Therefore, processed and fabricated materials will contain significant, but varying, amounts of hydroperoxide and peroxide functionalities, depending on the degree to which the material is stabilized with antioxidants and on the degree of thermo-oxidative exposure.

With plastics and synthetic fibers, compounding to incorporate stabilizer, filler, lubricant, pigment, etc., requires several minutes exposure at 175 – 300 °C. Subsequent fabrication into final articles usually requires < 10 min at temperatures that vary according to the fabrication process:

Fabrication process	Temp., °C
Injection molding	175 – 340
Film blowing	175 – 260
Film extrusion	175 – 260
Blow molding	175 – 230
Fiber spinning	230 – 350
Rotomolding	280 – 340

Processing at high temperature can have a significant impact on a polymer. For example, polypropylene was extruded a total of five times at 260 °C in a 2.54 cm laboratory extruder. Table 1 shows the melt flow rates for pellets retained from the first, third, and fifth extrusions. The large increase in melt flow rate of the unstabilized sample reflects considerable polymer chain cleavage during processing. Melt flow rate determinations and viscosity measurements are convenient and sensitive methods for following changes in average molecular masses of polymers.

Table 1. Multiple extrusion of polypropylene at 260 °C

Antioxidant (AO) stabilizer	Melt flow rate (g/10 min) after extrusion number:			
	0	1	3	5
None	4∗	8	14	23
0.1 % phenolic AO	–	6	7	9

∗ With 0.5 % phenolic AO

The influence of processing on the thermal stability of a polymer can be seen in Table 2. polypropylene samples (0.6 mm plaques), after one, three, and five extrusions at 260 °C, were oven aged at 150 °C; the deleterious effect of additional processing on thermal stability is clearly evident.

Table 2. Influence of processing on thermal stability of polypropylene

Antioxidant (AO) stabilizer	Hours to failure after extrusion number:		
	1	3	5
None	<20	<20	<20
0.1 % phenolic AO	510	400	330

The *ease of oxidation* of organic materials is related to the tendency of the substrate to participate in free-radical reactions with oxygen. Substrates that contain carbon – carbon unsaturation with allylic hydrogen atoms are particularly prone to oxidation. For this reason, unsaturated polymers, notably unvulcanized elastomers, and foods with unsaturated fats and oils oxidize easily. The impact of unsaturation is shown by the following comparative polymer data (0.1 % phenolic AO, 100 °C, 0.6 mm plaques)

Polymer	Hours to failure	
polypropylene	10000 [a]	↓
Impact polystyrene	500 [b]	Increasing degree of unsaturation
Styrene – butadiene rubber	69 [c]	
Polybutadiene rubber	15 [c]	↓

[a] Disintegration.
[b] Color formation.
[c] Gel formation.

3. Reaction Mechanisms

3.1. Autooxidation Mechanisms

The work on autooxidation carried out at the Natural Rubber Producers' Research Association in England in the 1940s and early 1950s was a major contribution to understanding autooxidation and stabilization reactions. The work of Bateman [3], Bolland [4], Gee, and Ten Have, among others, showed the oxidation of hydrocarbon materials to:

1) be free radical in nature,
2) have a period of inhibition,
3) have the properties of an autocatalytic chain reaction,
4) yield hydroperoxides as primary oxidation products.

Autooxidations have three distinct steps:

Initiation:

$$\mathrm{ROOH} \xrightarrow{k_1} \mathrm{RO}\cdot + \mathrm{HO}\cdot$$

Propagation:

$$\mathrm{ROO\cdot(RO\cdot, HO\cdot) + RH \xrightarrow{k_2} ROOH + R\cdot} \quad (1)$$
$$\mathrm{R\cdot + O_2 \xrightarrow{k_3} ROO\cdot}$$

Termination:

$$\mathrm{2\,ROO\cdot \xrightarrow{k_4} [ROOOOR] \longrightarrow ROOR + O_2} \quad (2)$$
$$\mathrm{2\,R\cdot \xrightarrow{k_5} RR}$$
$$\mathrm{R\cdot + ROO\cdot \xrightarrow{k_6} ROOR}$$

In most instances, when the oxygen concentration is not limiting, termination involves mainly peroxy radicals.

In his work on the oxidation of ethyl linoleate, a model for unsaturation in elastomers and, incidentally, also for fatty foods, BOLLAND [5] identified hydroperoxides as the main products of oxidation. He also showed ethyl linoleate hydroperoxide to be an initiator of ethyl linoleate oxidation. The rate expression in this instance is:

$$\frac{\mathrm{d}c_{\mathrm{ROOH}}}{\mathrm{d}t} = k_2 c_{\mathrm{RH}} \sqrt{\frac{k_1 c_{\mathrm{ROOH}}}{k_4}}$$

The termination of secondary peroxy radicals proceeds through a tetroxide intermediate to yield *sec*-alcohols and ketones [6]:

$$\mathrm{2\,R_2CHOO\cdot \longrightarrow R_2CHOH + R_2C{=}O + O_2}$$

Tertiary peroxy radicals, on the other hand, do not terminate directly. In this case the metastable tetroxide intermediate decomposes to yield alkoxy radicals and oxygen [7–9]:

$$\mathrm{2\,ROO\cdot \longrightarrow [ROOOOR] \longrightarrow 2\,RO\cdot + O_2} \quad (3)$$

where R contains a *tert*-carbon atom attached to oxygen. With cumylperoxy radicals, about 10 % of termination takes place by Reaction (2) to yield dicumyl peroxide, and 90 % proceeds by Reaction (3) [9]. The cumylalkoxy radical reacts further and eventually terminates as a methylperoxy radical:

$$\mathrm{RO\cdot \longrightarrow CH_3\cdot + C_6H_5COCH_3}$$
$$\mathrm{CH_3\cdot + O_2 \longrightarrow CH_3O_2\cdot}$$
$$\mathrm{CH_3O_2\cdot + RO_2\cdot \longrightarrow CH_2O + ROH + O_2}$$

where R is $C_6H_5C(CH_3)_2$.

Oxidation can start in a hydrocarbon at ambient temperature because most commercial organic materials are subjected to high temperature, e.g., during processing, fuel and lubricant refining, and food preparation. Small but detectable quantities of peroxides form and serve as initiators of autooxidation. The main product of autooxidation, hydroperoxide, is an initiator of autooxidation. This is the reason autooxidation is autocatalytic.

The plot of oxygen uptake (Fig. 1) for high-density polyethylene (HDPE) at 100 °C exhibits the autocatalytic nature of autooxidation. During an induction period of about 35 h, little oxygen is absorbed. Once initiator concentration is sufficiently high and oxidation inhibitors, if any, are consumed, however, oxygen consumption increases rapidly to a steady rate. This behavior is characteristic of organic materials undergoing autooxidation.

Figure 1. Oxygen uptake curve of Du Pont Alathon 5496 HDPE at 100 °C and 101.3 kPa

3.2. Antioxidant Mechanisms

Antioxidants are classified as either radical trapping (chain breaking) or peroxide decomposing, terms that describe the mechanisms by which they function.

3.2.1. Radical Trapping

Radical trapping antioxidants (AH) function by reaction with (trapping) the propagating *oxygen free radicals* in autooxidation:

$$ROO\cdot + AH \longrightarrow ROOH + A\cdot \quad (4)$$

The antioxidant thus competes with the organic substrate (RH) as a source of hydrogen for peroxy radicals in the usual autooxidation sequence (Eq. 1). For effective radical trapping antioxidants, Reaction (4) is much faster than Reaction (1). In addition, the radical A · must be stable and not abstract hydrogen atoms from the organic substrate; i.e., it should not function as a chain-transfer agent:

$$A\cdot + RH \not\longrightarrow AH + R\cdot \quad (5)$$

Otherwise, the antioxidant does not become a chain terminator but only transfers the propagation of oxidation from one molecule to another.

Radical trapping antioxidants, e.g., hindered phenols and secondary aromatic amines in particular, react with oxygen radicals (peroxy and alkoxy) almost exclusively. That they usually do not trap carbon free radicals efficiently is a distinct disadvantage. Trapping a *carbon free radical* (Eq. 6) is the preferred radical trapping reaction because it reduces to zero the oxidative chain length (the average number of oxygen molecules consumed in a chain reaction), and markedly reduces hydroperoxide formation. The usual radical-trapping reaction is represented by Equation (4).

$$R\cdot + AH \longrightarrow RH + A\cdot \quad (6)$$

A new class of radical-trapping stabilizers, the hindered amines trap alkyl radicals (see Section 4.5).

Even though they do not reduce the oxidative chain length to zero, as would be preferred, radical-trapping antioxidants are very effective in reducing the oxidative chain length. For example, 1,4-benzohydroquinone at 0.03 % (mole fraction of hydroquinone to ester 9×10^{-4}) reduced the oxidative chain length for the benzoylperoxide-initiated, uninhibited oxidation of ethyl linoleate from 241 to one [10]. This means that in the uninhibited reaction, 241 molecules of oxygen were consumed and 241 molecules of hydroperoxide were formed in the chain reaction following the generation of one initiating radical. With the antioxidant present, only one molecule of oxygen was consumed and one molecule of hydroperoxide was formed per initiating radical. Both the uninhibited and the inhibited oxidative chain lengths vary with the substrate; however, stabilization by antioxidants always results in significant lowering of chain lengths.

3.2.2. Peroxide Decomposing

Peroxide decomposing antioxidants reduce the hydroperoxidic and peroxidic products of oxidation to more innocuous compounds, usually alcohols or ethers. Because peroxides are initiators of oxidation, their removal from organic materials is important in the inhibition of oxidation. The two major classes of peroxide decomposing stabilizers are trivalent phosphorus compounds and thiosynergists (see Sections 4.3 and 4.4).

Trivalent phosphorus compounds– phosphites and phosphonites – function as peroxide decomposers by abstracting peroxidic oxygen from hydroperoxides and peroxides, and reducing them. The phosphorus compounds are oxidized to phosphates or phosphonates:

$$(RO)_3P + R'OOH \longrightarrow (RO)_3PO + R'OH$$

Thiosynergists, mainly esters of thiodipropionic acid, function mainly at elevated temperatures ($>100\,°C$) both by direct reaction with hydroperoxides and by the nonradical decomposition of hydroperoxides catalyzed by the acidic oxidation products of the thiosynergists. This latter reaction is similar to the acid-catalyzed decompositions of cumene hydroperoxide used to manufacture phenol and acetone (→ Acetone).

3.3. Metal Deactivators

Metal deactivators are effective in reducing the particularly deleterious effects that copper in wires and cables has on polyolefin insulation. Copper is a particularly severe agent for degrading polymers by thermal oxidation. Metal deactivators are postulated to function by deactivating copper to oxidation by complexation at the polymer – metal interface (see Section 4.6).

4. Antioxidant Classes

4.1. Hindered Phenols

Hindered phenols are a major class of antioxidants. They are presently used as radical-trapping agents in plastics, elastomers, synthetic fibers, fuels, lubricants, and foods. Steric hindrance is provided by bulky substituents in positions on the ring ortho to the hydroxyl group. These bulky substituents influence the specificity of the phenols by blocking phenoxyl radicals from abstracting hydrogen atoms from organic substrates.

2,6-Di-tert-butylphenol [*128-39-2*] is the most widely used functionality in commercial hindered phenolic antioxidants. This group is effective and easily made at moderate cost by the ortho alkylation of phenol by olefins using an aluminum alkoxide alkylation catalyst [11], (→ Acylation and Alkylation, Chap. 2.1.4.):

Structures of common phenolic antioxidants are included in Table 3. A more comprehensive list of phenolic and other antioxidants can be found in [12].

Substituents in the 4-position of 2,6-di-*tert*-butylphenol influence the solubility of the antioxidant. Moreover, high-molecular-mass substituents influence the migration and extractability of antioxidants, reducing their extraction from food-packaging plastics, and making such antioxidants suitable for use as indirect food additives. The 4-substituent can also influence the reactivity of the hindered phenol, making some compounds more suitable for certain substrates, such as unsaturated elastomers.

The mechanism of the reaction of hindered phenols with alkylperoxy radicals, as a model for chain propagating radicals, was investigated. In oxidizing organic substrates [13], [14]. In solution each hindered phenolic moiety consumed two peroxy radicals:

$$\mathrm{ROO}\cdot + \mathrm{AH} \longrightarrow \mathrm{ROOH} + \mathrm{A}\cdot \qquad (7)$$
$$\mathrm{ROO}\cdot + \mathrm{A}\cdot \longrightarrow \mathrm{ROOA}$$

4-Alkylperoxycyclohexadienones were isolated:

where R, R′, R″ are CH_3 or t-C_4H_9.

Compounds with 4-methyl substituents also yielded *stilbenequinone* derivatives (**15**), arising from the following reaction sequence:

Stilbenequinones have very high-extinction coefficients in the visible portion of the spectrum, and can contribute significant color to the materials in which they are incorporated. Stilbenequinones are serious problems, particularly in plastics stabilization because amounts as small as 5×10^{-6} parts are sufficient to impart a yellow color to the plastic, which is objectionable in colorless or white plastic articles.

The antioxidant efficiency of phenolic antioxidants as well as the degree of chain transfer have been measured [14]. The *antioxidant efficiency* is defined as $2k_a/k_r$, where k_a is the rate constant for Equation (4) and k_r is the rate constant for Equation (1). Efficiencies were found to be 32 for 2,4,6-tri-*tert*-butylphenol and 33.5 for 2,6-di*tert*-butyl-4-methylphenol. No chain transfer (Eq. 5) was found with either antioxidant.

The 4-alkylperoxy-4-alkyl-2,6-di-*tert*-butylcyclohexadienones have been formed in the presence of relatively high concentrations of alkylperoxy radicals. Because that situation does not usually exist in inhibited oxidation of organic materials under conditions of use, the normal reaction in plastics is the disproportionation of two phenoxy radicals. This reaction regenerates starting phenol and quinone methide (**16**):

16

Quinone methides have limited stability and react to yield a complex mixture of products [15], [16].

4.2. Aromatic Amines

Secondary aromatic amines for use in elastomer stabilization were among the first antioxidants. The main classes are diarylamines, amine – ketone condensation products (e.g., aniline – acetone condensates), and substituted *p*-phenylenediamines. Most are colored and form highly colored oxidation products. Thus, their uses are generally limited to those for which discoloration is not a drawback, e.g., carbon-black-filled, vulcanized elastomers are a major application.

In spite of their long history of use, the *mechanisms of action* of aromatic amine antioxidants are not as well understood as are those of hindered phenolic antioxidants. To a great extent this is because of the mixture of oxidation products obtained from aromatic amines, and the complex composition of some of the aromatic amine antioxidants. Nevertheless, the general features of the mechanisms are known.

The secondary amines serve as a source of hydrogen atoms, which are abstracted by peroxy radicals (Eq. 4) to yield relatively stable aminyl radicals. The same competitive reactions as found with hindered phenols are the key to the activity of amines as antioxidants.

The *antioxidant efficiencies* of secondary aromatic amines were found to be comparable to those of hindered phenols in the sensitized oxidation of 9,10-dihydroanthracene [17]. The intermediate aminyl radicals had a low tendency to abstract hydrogen atoms from polymers. They were similar in this behavior to hindered phenoxyl radicals. Tertiary amines showed no oxidation retarding properties. *N,N′*-Di-*sec*butyl-*p*-phenylenediamine was particularly efficient in trapping peroxy radicals; it trapped two peroxy radicals per diamine molecule, leading to the formation of quinone imide.

In the diphenylamine-inhibited oxidation of cumene at 68.5 °C, diphenylaminyl radicals were converted in significant amount to nitroxyl radicals; about 20 % of the initial diphenylamine was isolated as diphenyl nitroxide [18].

The *N*-oxyl may eventually trap an alkyl radical:

(8)

The ratio of the rate constants, k_8/k_7, is about ten in the oxidation of styrene:

(9)

Reaction (9) therefore is favored in the presence of significant oxygen. However, in the virtual absence of oxygen, Reaction (8) is important, as evidenced by the ability of 4,4-dimethoxydiphenyl nitroxide to function as an inhibitor for styrene polymerization initiated by azobisisobutyronitrile (AIBN) at 60 °C [19].

4.3. Organosulfur Compounds

The usefulness of organosulfur compounds as stabilizers for organic materials was recognized early. Metal salts of dialkyldithiocarbamic acids (→ Dithiocarbamic Acid and Derivatives), zinc dialkyldithiophosphates, and esters (dilauryl, dimyristyl, distearyl) of thiodipropionic acid have become important commercial antioxidants for the stabilization of diverse materials: lubricants, elastomers, and plastics. Several comprehensive reviews have been published on these compounds as antioxidants [20–23].

Mechanisms of Action. Organosulfur antioxidants decompose hydroperoxides by *nonradical reactions.* The effectiveness of various

organosulfur compounds, i.e., alkyl- and aryl-sulfides, alkyl- and arylthiols, and a zinc dialkyldithiophosphate in decomposing cumene hydroperoxide was determined in mineral oil at 150 °C [24]. The most effective compounds were zinc di(4-methylpentyl)-2-dithiophosphate, *n*-dodecylthiol, and a sulfonic acid. All reactions gave high yields of phenol, implying that they proceeded by acid catalysis [25].

Oxidation and decomposition products of the organosulfur compounds are responsible for inhibiting the oxidation of organic materials by decomposing the hydroperoxides. Sulfur dioxide, one of these terminal oxidation products, is a highly effective hydroperoxide decomposer [26]. Sulfides and disulfides react with hydroperoxides to yield sulfoxides and thiosulfinates:

$$RSR + R'OOH \longrightarrow RS(O)R + R'OH$$
$$RSSR + R'OOH \longrightarrow RS(O)SR + R'OH$$

Sulfenic acid, RS(O)H, and thiosulfoxylic acid, RSS(O)H, are decomposition products of sulfoxides and thiosulfinates. Each molecule of these acids is capable of decomposing many hydroperoxide molecules [27]. In addition higher oxidation products of sulfenic and sulfoxylic acids, i.e., sulfonic, thiosulfurous, thiosulfuric, and sulfuric acids, and sulfur dioxide are also catalytic hydroperoxide decomposers [27]. A large number of active hydroperoxide decomposers are generated by the oxidation of sulfides and disulfides with hydroperoxides.

Dilauryl thiodipropionate (**17**) [*123-28-4*], (DLTDP) is a common thiosynergist for polyolefin stabilization. Its mechanism of action is similar to relatively simple aromatic and aliphatic sulfide and disulfide model compounds [28]. The DLTDP sulfoxide (**17a**) was thermally unstable at 150 °C and decomposed to a gas (SO_2, H_2S, H_2O), a liquid (containing lauryl acrylate), and a solid (a complex mixture of several compounds, including the sulfenic acid, $H_{25}C_{12}O_2CCH_2CH_2SOH$) [28]. In addition to hydroperoxide decomposition, a second mechanism for DLTDP activity involves the reaction of DLTDP (**17**) with the peroxycyclohexadienone reaction product of a hindered phenol. The hindered phenol was regenerated in 41 % yield [28]:

This mechanism can be important in oxidations where significant amounts of peroxycyclohexadienone products are formed from hindered phenols, and in the performance of 2,6-diphenyl-4-octadecyloxyphenol [29].

A third mechanism for thiosynergists comes from the observation that zinc dialkyldithiophosphates, zinc dialkylxanthates, and zinc dialkyldithiocarbamates, inhibit the azobisisobutyronitrile oxidation of squalene at 60 °C [30], [31]. The inhibition is the result of peroxy radical trapping involving electron transfer from sulfur in the zinc salts to the peroxy radicals. Disulfides and zinc peroxides are the products:

$$[(RO)_2P(S)S]_2Zn + 2\,R'OO\cdot \longrightarrow$$
$$(RO)_2P(S)S{-}S(S)P(OR)_2 + Zn(OOR')_2$$

Hydroperoxide decomposition is generally the main mechanism of stabilization by organosulfur compounds. The relative importance of other mechanisms, peroxy radical trapping and hindered phenol regeneration, depends on the stabilizers and circumstances of use.

Thiosynergism. A *synergism of action* exists between radical trapping antioxidants (hindered phenols or secondary aromatic amines) and peroxide-decomposing antioxidants (zinc dialkyldithiophosphate or dialkyl sulfide) in the stabilization of mineral oil at 155 °C and 180 °C [24]. Sulfoxides inhibit oxidation only after the absorption of a small amount of oxygen. Sulfoxides, RS(O)R, and thiosulfinates, RS(O)SR, were especially effective inhibitors for the oxidation of squalene at 75 °C [32].

Esters of thiodipropionic acid play a key role in the high-temperature stabilization of polyolefins by hindered phenols. Figure 2 shows the considerably longer lifetimes obtained with the combination of a hindered phenol and DLTDP [33]. All samples contained 0.4 wt% of stabilizer. Curves a and b depict the lifetimes obtained with DLTDP and hindered phenol, respectively; c is calculated from a and b; and d is a plot of the experimental values from actual compositions of hindered phenol and DLTDP tested at 140 °C. The markedly superior performance shown by the actual mixtures is a result of synergistic interaction between the two stabilizers, the one basically radical trapping, the other hydroperoxide decomposing.

Thioesters are effective primarily when polymers are in the solid state and are at temperatures < 160 °C. This is in contrast to phosphites (see Section 4.4), another class of hydroperoxide decomposers, which are effective in protecting polymers in the molten state during processing and fabrication, usually at temperatures $\gg 160$ °C.

Figure 2. Synergists in heat stabilization
a) DLTDP (dilauryl thiodipropionate); b) Irganox 1010; c) Calculated; d) Experimental

4.4. Phosphorus Compounds

Trivalent phosphorus compounds, i.e., phosphites and phosphonites, are practically the only types of phosphorus compounds being used commercially as antioxidants. The only other major class is zinc dialkyldithiophosphate, which finds use primarily in lubricants. Its mode of action is discussed in Section 4.3.

Mechanisms of Action. Trivalent phosphorus antioxidants generally function by reducing hydroperoxides and peroxides to alcohols and ethers:

$$(RO)_3P + R'OOH \longrightarrow (RO)_3PO + R'OH$$

Neither the phosphate nor the alcohol is an oxidation initiator. The reaction between phosphites or phosphonites and peroxy compounds takes place at moderate temperature but, unfortunately, is stoichiometric. Therefore the effectiveness ceases once all the trivalent compound is oxidized.

Phosphites also function as alkoxy and peroxy radical trappers, as in reactions (10) and (11). Stabilization results if (**18**) is a hindered phenoxy radical with a low tendency to abstract hydrogen from polymer, i.e., if it is comparable in activity and stability to radicals generated from effective hindered phenolic antioxidants [34]:

$$(RO)_3P + R'OO\cdot \longrightarrow (RO)_3\dot{P}OOR' \qquad (10)$$
$$(RO)_3\dot{P}OOR' \longrightarrow (RO)_3P{=}O + R'O\cdot$$

$$R'O\cdot + (RO)_3 \longrightarrow (RO)_3\dot{P}OR' \qquad (11)$$
$$(RO)_3\dot{P}OR' \longrightarrow RO)_2POR' + RO\cdot$$

18

Certain cyclic phosphites, notably catechol phosphites, are catalytic hydroperoxide decomposers, their corresponding phosphates functioning as strong acids [35]:

where R is alkyl

Thiophosphites, thiophosphates, and easily hydrolyzable phosphates also are catalytic hydroperoxide decomposers. The thiophosphorus compounds are oxidized to acidic products that function as the active agents [36].

Uses. Phosphites, such as tris(nonylphenyl) phosphite (TNPP) (**19**), have been used commercially for about 40 years as stabilizers for unsaturated elastomers. In spite of limited stability to hydrolysis and attendant corrosion problems, TNPP continues to be used for low-cost antioxidant applications. More sophisticated trivalent phosphorus compounds have been marketed primarily to minimize molecular mass changes in polyolefins during compounding and fabrica-

tion. Several of these newer products are regulated by the FDA as indirect food additives for plastic food packaging. They are used with hindered phenolic antioxidants not only to minimize molecular mass changes, but also to reduce the color development on high-temperature processing and subsequent use that is usually associated with hindered phenols (Table 4; see above). The data in Table 5 show the reduction in concentration of phosphites during high-temperature processing of polypropylene. These results emphasize the sacrificial role of phosphite stabilizers and suggest they are not suitable candidates for long-term stabilization. However, by inhibiting polyolefin thermooxidative degradation during high-temperature processing, phosphites help prolong polymer life.

* Stabilizers identified in Table 4.

Table 6 (see next page) gives the major commercial trivalent phosphorus compounds used as antioxidants for plastics and rubbers.

4.5. Hindered Amines

Hindered amines are used primarily as light stabilizers but were also recognized early as stabilizers against thermooxidative degradation. The following data [37] summarize the antioxidant activity of hindered amine stabilizer in oven aged (120 °C) polypropylene multifilaments (8000/396 den):

Stabilizer	Days to embrittlement
Hindered amine stabilizer, O.1 %	47
Hindered amine stabilizer, 0.25 %	80
Hindered amine stabilizer, 0.5 %	110
Phenolic antioxidant-1, 0.1 %	14
Phenolic antioxidant-2, 0.1 %	20

In certain instances, particularly at moderate temperatures (< 120 °C), some hindered amines are more effective than hindered phenols for the stabilization of polypropylene stretched tapes [38]. These results are in line with the generally accepted *mechanisms of action* of hindered amines:

1) trapping of carbon free radicals by hindered amine nitroxyls [39]

2) trapping of peroxy radicals by hydroxyl amine ethers (reaction products from trapping carbon free radicals by hindered amine nitroxyls) with the regeneration of nitroxyls and formation of peroxides [40]

$$>NOR + R'O_2\cdot \longrightarrow >NO\cdot + R'OOR$$

3) complexing of hydroperoxides by hindered amines and hindered amine nitroxyls [41].

Trapping carbon free radicals is preferable to trapping peroxy radicals for purposes of stabilization because the former assures the oxidative chain length will be zero (no hydroperoxide formed), whereas trapping peroxy radicals yields one or more hydroperoxide products.

The complexation of hydroperoxides by stabilizer molecules is also a real advantage because it effectively increases the stabilizer concentration in the vicinity of the main species responsible for initiating oxidation.

Table 7 contains the main hindered amines available commercially.

4.6. Metal Deactivators

Metal deactivators were developed primarily to increase the lifespan of polyolefin insulation in contact with copper conductors in communications wire. Phenolic antioxidants alone are not effective in providing long-term stability. Copper is a prooxidant in polyolefin oxidation. It functions as a catalytic decomposer of hydroperoxides, generating alkoxy and peroxy radical initiators of oxidation:

$$\begin{array}{l} ROOH + Cu^{+} \longrightarrow RO\cdot + Cu^{2+} + OH^{-} \\ ROOH + Cu^{2+} \longrightarrow ROO\cdot + Cu^{+} + H^{+} \\ \hline 2\,ROOH \longrightarrow ROO\cdot + RO\cdot + H_2O \end{array}$$

In the absence of metal deactivators, copper penetrates polyethylene via oxidation reactions, yielding copper carboxylates among many products [42]. Metal deactivators markedly reduce the rate of copper penetration and are postulated to function by complexing copper at the polymer – metal interface and within the polymer [42]. Table 8 (see page after next) shows the severe effect of copper on the heat stability of polyethylene and the effectiveness of two different metal deactivators in reducing thermal degradation.

Table 8. Thermal stability of poly(propylene – ethylene) compression molded plaques containing embedded copper screen

0.2 % Irganox1010 +	Hours to failure				
	120 °C		40 °C	150 °C	
	Cu	No Cu	Cu	No Cu	Cu
No metal deactivator	460	1710	360	850	100
0.2 % Irganox MD 1024	1320	1870	570	760	250
0.2 % Eastman OABH	1360	1780	500	760	250

The major commercially available metal deactivators are Irganox MD-1024 [*32687-78-8*], (**32**); Eastman Inhibitor OABH [*6629-10-3*], (**33**); Naugard XL-1 [*70331-94-1*], (**34**).

32

33

34

The amide or hydrazide functionalities complex copper, and are responsible for the inhibition activity. Normally, a combination of a hindered phenol and a metal deactivator is used to stabilize polyolefins in the presence of copper. However, because Irganox MD 1024 and Naugard XL 1 contain both phenolic and nitrogen groups, they can be used as the sole stabilizers for that application.

Metal deactivators are also used with hindered phenols for the stabilization of filled polyolefins, where metallic impurities in fillers adversely affect the thermooxidative stability of polymers [43].

5. Practices in Stabilization with Antioxidants

Specialized practices have evolved for each of the four major substrate classes that are stabilized with antioxidants:

1) foods,
2) fuels,
3) lubricants, and
4) polymers.

Some antioxidants are used in more than one substrate class. For the most part, however, each class has its own stabilizer types and amounts. Some antioxidant practices are common to all substrate classes: antioxidants for each class are selected on the basis of effectiveness, solubility, and cost. In the United States, antioxidants used in food and food-packaging plastics are limited to ones regulated by the Food and Drug Administration (FDA) for these uses.

5.1. Stabilization of Food

The antioxidants most commonly used to stabilize food against autooxidation are butylated hydroxytoluene (**5**), see Table 3; butylated hydroxyanisole (BHA) (**35**) [*25013-16-5*], mixture of 2- and 3-*tert*-butyl-4-methoxyphenol, Tenox BHA (Kodak); and *n*-propyl gallate (**36**) [*121-79-9*], 3,4,5-trihydroxybenzoic acid propyl ester, Tenox PG (Kodak).

35

36

These antioxidants may be used directly in foods governed by FDA regulations. They are used to protect fats and oils during frying and retain activity during storage. In general they are used to prevent oxidation of foods, which results in deterioration of flavor and odor. Butylated hydroxytoluene is used in packaging materials for cookies, cold cereals, etc., where the relatively high-vapor pressure of BHT permits it to transfer from the packaging material to the contained food.

Use of BHT and BHA as direct food additives has been questioned as a result of published toxicity studies showing a higher than normal incidence of benign, precancerous, and cancerous tumors in test animals having been fed the antioxidants. However, detailed evaluations of the studies have always been resolved in favor of

the continued use of both antioxidants for food. A number of studies have supported the safety of BHT for the stabilization of food [44].

5.2. Stabilization of Fuels

Hydrocarbon fuels, gasoline, jet fuel, and fuel oil, are subject to autooxidation (→ Aviation Turbine Fuels, → Automotive Fuels). Autooxidation of fuels causes deposits that can foul carburetors, valves, pumps, and other precision equipment. Acidic oxidation products corrode critical metal parts in fuel systems. Hydroperoxide oxidation products are undesirable in gasoline because their rapid homolysis under combustion conditions leads to preignition, thereby lowering octane performance.

The addition of antioxidants to fuels effectively stabilizes them against autooxidation during storage. Both phenolic and aminic antioxidants are used, sometimes in combination. The main phenolic antioxidants for fuels are BHT (**5**); 2,4-dimethyl-6-*tert*-butylphenol, and 2,6-di*tert*-butylphenol. Among the aminic antioxidants, *N,N′*-di-*sec*-butyl-*p*-phenylenediamine has been of the greatest importance historically and continues to be used in fuels. However, other aminic antioxidants, some proprietary, including *p*-phenylenediamine with *N*-isopropyl or *N*-heptyl substituents, are also used.

Use levels of antioxidants for fuel stabilization are presently on the order of 0.5 – 1 kg per 1000 barrels of fuel (1 U.S. barrel = 159 L). This level is markedly lower than the 5 – 7 kg and more per 1000 barrels used in the past. The lower stabilizer requirement has come about because the composition of, and the production processes for fuels, especially gasoline, have increased the oxidative stability of base fuels.

5.3. Stabilization of Lubricants

Lubricating oils (→ Lubricant and Related Products) usually operate at relatively high temperature in gas turbines, steam turbines, jet engines, and crankcases of internal combustion engines. The performance requirements of stabilizers for these conditions are very demanding. Antioxidants minimize the deterioration of these lubricants by retarding viscosity increase, metal corrosion (usually controlled in conjunction with a corrosion inhibitor), and formation of acid, sludge, resins, and lacquers.

Mineral oil lubricants (gas turbines, steam turbines) are stabilized with 0.5 – 1.0 % of zinc dialkyldithiocarbamates in combination with 0.5 – 1.0 % of a phenolic antioxidant (BHT or 2,6-di-*tert*-butylphenol) or with an aminic antioxidant (octylated or nonylated diphenylamine, or phenyl α-naphthylamine or its derivatives).

Mineral crankcase oils may contain 0.5 – 1.0 % zinc dialkyldithiophosphates, which function as radical-trapping and peroxide-decomposing antioxidants in addition to their antiwear activity. These additives often are supplemented with sulfurized olefins (obtained by reacting sulfur with olefins), and aminic and phenolic antioxidants. The trend in the United States to unleaded gasolines and catalytic convertors has put pressure on the lubricant manufacturer to remove phosphorus-containing additives from crankcase oils, but so far with little success.

Mineral lubricants for diesel engines are stabilized with 0.5 – 1.0 % zinc diaryldithiophosphates, which are more thermally stable than the dialkyl derivatives and occasionally are supplemented with octylated or nonylated phenyl-α-naphthylamine.

Synthetic lubricants, both polyester and polyolefin types, are stabilized with 0.5 – 1.0 % alkylated phenyl-α-naphthylamine and/or alkylated diphenylamine.

5.4. Stabilization of Polymers

Virtually all commercial organic polymers, including elastomers, thermoplastics, synthetic fibers, and adhesives, are susceptible to oxidative degradation during processing and end use, with resulting reduction in physical properties and discoloration. Most polymers would not be useful without the small amounts of stabilizing additives, antioxidants, and processing stabilizers that are added to permit them to survive high-temperature processing and other thermooxidative conditions.

Antioxidant properties that influence performance include compatibility or solubility in the

polymer or other substrate, volatility, discoloration resistance, and thermal stability. Antioxidants are selected on the basis of how important these properties are for the specific application and how well antioxidants meet them.

Additional factors in selecting antioxidants include the desired lifetime, the product thickness (samples of small cross section are more difficult to stabilize than thick samples); other components of the formulation, i.e., fillers, pigments, and flame retardants that may influence the effectiveness of the antioxidant, use conditions, FDA status, and cost performance. The last is a key consideration because it is not the selling price of the antioxidant that should be determinant but the cost of stabilization to get the job done.

5.4.1. Elastomers (→ Rubber, 1.Survey)

Many different stabilization practices have evolved for polymers over the years. Elastomers, which commonly exhibit carbon – carbon unsaturation in the backbone, are particularly sensitive to oxidative degradation. They require stabilization during drying and storage in the uncompounded state as well as subsequently in the vulcanized forms. Both nonstaining and staining antioxidants are used. *Nonstaining, hindered phenolic antioxidants,* such as BHT (**5**), *phosphites*, such as tris(nonylphenyl phosphite) (**19**), and *nonstaining amines,* such as alkyl-substituted diphenylamines and alkyl-substituted phenyl-α-naphthylamines, are used when the final formulations are relatively light colored. However, because much of the production of elastomers is used in carbon-black-filled, vulcanized formulations, *staining antioxidants* may be used. These antioxidants contain dark-colored components capable of migrating into light-colored objects in contact with the vulcanized elastomer, causing objectionable discoloration or staining. Aryl- and alkyl-substituted *p*-phenylenediamine derivatives are commonly used as staining antioxidants for elastomers because they provide antioxidant as well as antiozonant activity. Other staining aminic antioxidants, such as aniline-acetone condensation products, also are used as antioxidants for elastomers.

Stabilization of elastomers against oxidation was historically among the earliest uses of polymer antioxidants [2]. Most were staining antioxidants could not be directly applied to other polymers. However, nonstaining antioxidants used in elastomers, hindered phenols, and phosphites particularly, and nonstaining amines, to a limited degree, are used also in other polymers.

5.4.2. Thermoplastics (→Thermoplastic Elastomers)

Stabilization in the early history of thermoplastics revolved around hindered phenols, such as BHT (**5**); 2,2′-methylenebis(4-methyl- 6-*tert*-butylphenol) (**3**), 4,4′-methylenebis(2,6-di-*tert*-butylphenol), 4,4′-thiobis(2-*tert*-butyl-5-methylphenol) (**14**), and other relatively simple phenolic antioxidants. These antioxidants were generally adequate for the limited stabilization demands of early thermoplastics. However, stabilization requirements became more demanding with the advent of polystyrene containing unsaturated elastomeric constituents for impact modification and especially with the introduction of polyolefins from Ziegler-Natta catalysis in the mid-1950s. More effective antioxidants were needed for these demanding applications. Today, sophisticated, relatively high-molecular-mass antioxidants, stabilize the bulk of commercial polymers (see Table 3). Although BHT continues to be used for the stabilization of thermoplastics, its relatively high-vapor pressure limits its use to low-demand applications.

Hydrocarbon thermoplastic polymers, which are the main consumers of antioxidants, *polystyrenes, polyolefins,* and *thermoplastic elastomers* are stabilized with phenolic antioxidants, phosphites or phosphonites, and thiosynergists; the composition and concentrations depend on life stage and end use, as shown in Table 9. These stabilizers are used to retard the loss of physical properties and to minimize discoloration of polymers that accompany thermooxidative degradation. The stability problems associated with these polymers are increased by recycling scrap from processing operations. Thus, some of the polymers may be processed one or more times, depending on the amount of scrap recycled.

Table 9. Practices in polymer stabilization

Life stage of polymer	Stabilizer	Usual concentration, ppm
Drying	antioxidant	<250
Storage	antioxidant	<250
Compounding	antioxidant	500 – 1000
	phosphite	500 – 1000
Fabrication	antioxidant	500 – 1000
	phosphite	500 – 1000
End-use		
low stress	same as compounding and fabrication	
thermally stressing	antioxidant	1000 – 5000
	thiosynergist	1000 – 5000
	phosphite	500 – 1000
weathering	antioxidant	0 – 1000
	phosphite	500 – 1000
	hindered amine	0 – 10000
	ultraviolet absorber	0 – 10000

Polyoxymethylene polymers (→ Polyoxymethylenes) are sensitive to hydrolysis so that in addition to 0.1 – 0.5 % hindered phenolic anti oxidants, 0.1 – 0.5 % of an acid – formaldehyde scavenger, such as cyanoguanidine, calcium ricinoleate, or terpolyamide, is also used.

Polyamides (→ Polyamides) discolor and their physical properties deteriorate as a result of thermal oxidation. Early in their history, polyamides were stabilized with copper halides and simple phosphites, sometimes even phosphorous acid. More recently, hindered phenols, notably *N,N′*−1,6-hexamethylene-bis-3-(3,5-di-*tert*-butyl- 4-hydroxyphenyl)propionamide (**8**), have been used at 0.1 – 0.5 % to stabilize nylon 6 and nylon 66. Polyamides with longer aliphatic chains, such as nylon 12, are stabilized with phenolic antioxidants, such as tetrakis[methylene(3,5-di-*tert*butyl-4-hydroxyhydrocinnamate)]methane (**2**).

Several polymers, notably *polyesters, acrylics,* and *polycarbonates,* are relatively thermally stable and require only small amounts of phosphites or hindered phenolic antioxidants to reduce discoloration.

5.4.3. Synthetic Fibers (→Fibers, 4. Synthetic Organic)

Synthetic fibers (polyamides, polyesters, and polyolefins) are stabilized in accordance with the practice for the corresponding thermoplastics, with the exception that the fibers are usually stabilized against photooxidation as well as thermooxidative degradation. Stabilization against photooxidation usually entails the use of hindered amines and ultraviolet absorbers as well as hindered phenolic antioxidants and phosphites.

5.4.4. Economic Aspects

The estimated consumption of antioxidants for plastics in the United States is given in Table 10 [45]. Table 11 shows the estimated consumption by plastic in the United States [46].

Table 10. Estimated consumption of antioxidants for plastics in the United States [45]

	$t \times 10^3$		
Antioxidant	1981	1982	1983
BHT	3.5	3.1	3.9
Other hindered phenols	5.6	5.2	7.3
Phosphites	3.2	2.9	4.5
Thioesters	2.7	2.4	3.1
Other	0.9	0.8	1.1
Total	15.9	14.4	19.9

	$\$ \times 10^6$		
Antioxidant	1981	1982	1983
BHT	12.8	10.2	15.9
Other hindered phenols	52.9	47.9	93.2
Phosphites	8.1	7.4	15.7
Thioesters	10.2	8.9	15.3
Other	4.0	3.4	6.7
Total	88.0	77.8	146.8

Table 11. Estimated consumption of antioxidants by plastic in the United States [46]

Plastic	Consumption, $t \times 10^3$		
	1981	1982	1983
ABS	4.6	3.7	4.4 (29 %)
Polyethylene	3.2	2.9	3.0 (20 %)

Other	1.5	1.3	1.4 (9 %)
Total	15.9	13.9	15.3 (100 %)

6. Food Safety Considerations

The safety of antioxidants used as both direct and indirect food additives is monitored rigor-

ously by food agencies in various countries, such as the FDA in the United States. In order to be permitted for use as stabilizers for food packaging, the safety of an indirect food additive needs to be demonstrated in subacute feeding studies with test animals, usually rats and dogs, and by migration studies with food-simulating solvents. The latter studies permit the estimation of levels of additives that may migrate into various types of foods from plastic packaging materials during filling, sterilization, and storage.

These data and the use profiles of the plastic packaging materials permit the calculation of *estimated daily intakes* (EDI) of the additive. Safety assessment is made by examining the EDI in light of the results of the feeding studies, especially the no-effect levels established by the feeding studies. For more details of the food safety and toxicologic aspects of antioxidants, see [47], → Foods, 3. Food Additives.

7. Test Methods to Evaluate Polymer Thermal Oxidative Stability

Antioxidants are used selectively for specific polymers and for specific applications. Therefore, selecting the best antioxidant is dependent on the performance characteristics of the antioxidants, their limitations, the formulation methods, and the oxidation behavior of the organic material to be stabilized. Evaluations must be conducted on a small scale in a finite time to predict field results, sometimes of thirty or more years.

7.1. Melt Processing

Melt processing is an important operation in the preparation of polymer formulations and of molded objects. However, the temperatures and high-shear rates involved in this processing degrade many polymers. The efficacy of stabilizers in preventing the degradation is usually evaluated by repeated melt processing.

The polymeric material is extruded and injection or blow molded. Then the processed material is chopped and reprocessed anywhere from 2 to 20 times, depending on the polymer and the application. Changes in melt viscosity are usually monitored after specific numbers of processing cycles.

Generally, little or no change in melt viscosity on repeated processing is desired, and additives are evaluated relative to one another. In addition, the color of samples on repeated processing is of considerable importance. Additives that prevent discoloration and are not themselves discolored are especially desirable.

7.2. Oven Aging

Oven aging at elevated temperature is another important test method used in the plastics industry. By this method, oxidative degradation is accelerated and the results obtained in relatively short times. However, to minimize the risks of extrapolation, *temperature* for oven aging is selected as close to the end-use requirement as is feasible from a testing time point of view. Results from at least three test temperatures permit extrapolation of failure times in apparent Arrhenius plots to a use temperature at which a life span estimate is desired.

The two most important variables in oven aging are the temperature and *air velocity* in the oven. Tests carried out in ovens without air movement can give misleading results because additives of low-molecular mass do not volatilize in static air ovens to the degree that they do in actual use and to the degree that they do in ovens with significant air velocities. The measurement of oven air velocities is difficult because considerable variations exist depending on the location in an oven. One method of overcoming this difficulty involves continuous rotation of specimens within the oven during the test period.

7.3. Oxygen Uptake

Another useful method for studying accelerated thermal oxidative degradation of polymers is oxygen uptake. Polymer samples are enclosed in a system with an oxygen atmosphere, and the rate of oxygen consumption is measured. Oxygen uptake methods have the advantage of being relatively rapid but require more specialized equipment. In addition, the results from oxygen uptake investigations are more difficult to relate

to end-use conditions because of the problem in extrapolating results in an oxygen atmosphere to normal atmospheric conditions.

7.4. Thermal Analytical Methods

Differential scanning colorimetry (DSC) and thermal gravimetric analysis (TGA) are useful methods that can provide information relatively quickly on the thermal stability of polymers. However, these measurements are usually carried out at temperatures above 180 °C, where many polymers are molten. Extrapolation of the results to performance in solid polymers at ambient temperature is questionable. On the other hand, DSC is very useful for quality control purposes once a formulation has been selected. Also TGA is particularly applicable in assessing the thermal properties of polymers, polymer formulations, and additives. Measurements by TGA are carried out using both programmed temperature increases and isothermal conditions. Temperatures at 1 %, 5 %, 10 %, and 50 % loss in sample mass, for example, are noted in the programmed temperature mode. In the isothermal mode, time to these mass losses are recorded.

7.5. Tests to Monitor Polymer Properties

Color and physical property measurements are the two most important ways of assessing performance of stabilizer compositions.

Color. Discoloration of plastic articles is usually undesirable. Color is generally monitored initially and after various exposure periods. Color may be assessed visually or measured instrumentally. Instruments generally read three parameters: L, the brightness of the specimen; a, the redness or greenness of the specimen; and b, the blueness or yellowness of the specimen; and tristimulus values X, Y, and Z. Various relationships of L, a, and b have been used to express specimen color. Yellowness index, a commonly used expression for relative color levels, is calculated for transparent samples from the tristimulus values:

$$\frac{1.28X - 1.06Z}{Y} \times 100$$

Table 12. Specific test details for selected polymers

Polymer	Property	Test conditions
ABS	color color impact strength	repeated processing oven aging oven aging
Polyacetal	weight loss weight loss	TGA 200 – 250 °C oven aging
Polyamides	solution viscosity color tensile retention of fiber	oven aging oven aging oven aging
Polycarbonate	color impact strength	oven aging oven aging
Polyester	color impact strength	oven aging oven aging
Polyethylene, low density	M_r – melt index gloss and clarity of film	repeated processing film blowing
Polyethylene, low density, cross-linked	tensile strength and elongation	oven aging
Polyethylene high density	M_r – melt index physical integrity embrittlement	repeated processing oven aging to
polypropylene	M_r – melt index physical integrity	repeated processing oven aging to embrittlement
Polystyrene, impact	color color impact strength	repeated processing oven aging oven aging
Polyvinyl chloride	color	oven aging
Polybutadiene rubber	M_r – Mooney viscosity gel content	oven aging oven aging
Thermoplastic elastomers	color tensile and elongation	oven aging oven aging

Physical Properties. Among physical test methods commonly used for evaluating the oxidative stability of polymers are tensile strength and elongation, and impact strength. *Elongation* is a more useful measure of oxidative degradation than tensile strength. *Tensile strength* may not be markedly affected by sample embrittlement, whereas elongation is much more sensitive and can provide evidence of degradation more readily. However, because both measurements are made simultaneously, it is not necessary to choose one over the other prior to testing.

Impact strength is measured in different ways depending on the end-use performance of articles made from the polymers in question. Among the methods used are unnotched Izod, notched Izod, tensile-impact, chip impact, falling dart, and high-speed-impact testing. Each has disadvantages and no single ideal impact test method exists. However, high-speed-impact testing with instrumented tups has several key advantages and would very likely be more universally adopted were it not for the relatively high cost of equipment, in the neighborhood of $ 50000 – $ 60000.

Monitoring of molecular mass changes on oxidative degradation is also a frequently employed technique. The melt index determination (Section 7.1) is a standard technique in the plastics industry. Molecular mass is also monitored by solution viscosity measurements, less frequently by gel permeation chromatography, and, in the case of elastomers, by Mooney viscosity measurements.

In undergoing oxidation, hydrocarbon polymers develop carbonyl groups (i.e., ketones, aldehydes, acids, esters, etc.). The monitoring of carbonyl absorbance by infrared spectroscopy is a useful technique for following the course of polymer oxidation.

For the specific test used to assess various polymer properties, see Table 12.

1. Arsenic

1.1. Introduction [1], [2]

Arsenic, As [*7440-38-2*], belongs to group 15 of the periodic table and has an atomic number of 33 and A_r 74.92. In compounds, it has oxidation states of +3, +5, and −3.

Arsenic is a bright silver-gray metal. Its surface tarnishes in humid air. Arsenic forms trigonal crystals, which are brittle and of average hardness (3 – 4 on the Mohs scale).

In addition to the metallic modification, there are other modifications, namely, yellow arsenic and three amorphous forms (β, γ, δ) [3]. Of these, black arsenic (the β form) is the best known. Black arsenic is formed as a coating (arsenic mirror) when arsenic hydride is passed through an incandescent glass tube and also, together with other modifications, when the vapor is rapidly cooled. Yellow arsenic is formed by the sudden cooling of arsenic vapor and consists of transparent, waxy, regular crystals. It is unstable and changes into metallic arsenic on exposure to light or on gentle heating. All amorphous modifications change into the metallic form above 270 °C.

Another form, brown arsenic (ϱ 3.7 – 4.1 g/cm^3), is either a special modification or simply a more finely divided form. This brown modification is obtained in the reduction of solutions of arsenic trioxide in hydrochloric acid with tin(II) chloride or hypophosphorous acid.

History [1], [2], [4]. The natural sulfides, realgar and orpiment, were known in pre-Christian times and had already been named by Aristoteles and his pupil Theophrast. In the first century a.d., Plinius mentioned sandarac (realgar) as occurring in gold and silver mines. The color of the yellow sulfide gave it the name orpiment. The Greek name "arsenikon" (fearless, brave, manly), which was given to the sulfides on account of their reactivity with metals, derived from the custom prevailing at the

10.1002/14356007.a03_113

time of classifying the metals as male or female. Subsequently, the name was applied to the metal itself. Many early authors described medicinal applications. DIOSKORIDES (first century A.D.) reported on the roasting of the sulfides and that they were used as remedies and artist's colors. In the fifth century A.D., OLYMPIODORUS described the production of the arsenic oxide As_2O_3. An incomplete description of metallic arsenic dating from the fourth century has also been found. The alchemists were more closely concerned with the sulfides of arsenic. They generally called the roasted product "white arsenic". Many considered the arsenic oxide, like sulfur, to be a basic constituent of metals. ALBERTUS MAGNUS apparently obtained the element in 1250; SCHROEDER described two methods of preparation in 1649. In 1733, BRANDT showed that white arsenic is the oxide of the metal. The alchemists were aware of the poisonousness of white arsenic (As_2O_3). Records show that the compounds of arsenic were extensively used by the poison brewers of the Middle Ages. In the Renaissance it was PARACELSUS who pioneered the use of arsenic compounds in medicine. Arsenic acid and arsenic hydride were discovered by SCHEELE in 1775.

1.2. Physical Properties [1], [2], [5]

Densities: metallic arsenic 5.72 g/cm^3 at 20 °C, yellow arsenic 2.03 g/cm^3
Melting point: 1090 K (817 °C) at 3.7 MPa
Sublimation point: 886 K (613 °C) at 0.1 MPa
Linear coefficient of thermal expansion: ca. $5 \times 10^{-6}\,K^{-1}$
Specific heat capacity: $0.329\,J\,g^{-1}\,K^{-1}$ at 291 K (18 °C), $0.344\,J\,g^{-1}\,K^{-1}$ on average between 273 K (0 °C) and 373 K (100 °C)
Electrical resistivity: $24 \times 10^{-6}\,\Omega \cdot cm$ at 273 K (0 °C)

The normal potential of arsenic with respect to the normal hydrogen electrode is ca. 0.24 V. Arsenic therefore comes between bismuth and copper in the electrochemical series.

1.3. Chemical Properties [1], [2], [5]

The various forms of arsenic have different behaviors in air. Whereas the amorphous forms remain unchanged for months in dry air, the crystallized α form turns black in a few days, as originally observed by BERZELIUS. Powdered, moist arsenic is oxidized to arsenic trioxide with evolution of heat. When heated in air, it burns with a bluish-white flame, forming dense vapors of arsenic trioxide. When heated, arsenic metal gives off a characteristic garliclike odor.

Concentrated nitric acid and aqua regia oxidize arsenic to arsenic acid; arsenic is oxidized to the +3 state by dilute nitric acid or concentrated sulfuric acid and by boiling alkali metal hydroxides in air. Hydrochloric acid has little effect on arsenic. Chlorine combines fierily with arsenic to form arsenic trichloride. When the metal is heated with sulfur, AsS, As_2S_3, or As_2S_5 is obtained, depending on the ratios used. A mixture of finely divided arsenic and potassium chlorate explodes on impact.

Arsenic combines with metals to form arsenides. When subjected to oxidizing roasting, arsenides give partly metal oxide and arsenous acid and partly basic arsenates. When subjected to chloridizing roasting, they give arsenic trichloride. On heating in the absence of air, a sublimate of arsenic metal is formed from the heavy metal arsenides, although the arsenic can only be partly removed even at very high temperatures.

With oxygen, arsenic forms three oxides, namely arsenic trioxide, As_2O_3; arsenic pentoxide, As_2O_5; and As_2O_4, which apparently contains both trivalent and pentavalent arsenic. The first two oxides may be regarded as acid anhydrides. Arsenous acid is derived from arsenic trioxide and can only exist in aqueous solution. Its well-known salts are the arsenates(III) (formerly arsenites). Arsenic acid is derived from arsenic pentoxide. Its salts, the arsenates, generally correspond to the phosphates in their stoichiometry. However, solid arsenic acids that correspond to the phosphorus acids are not known; instead, $H_3AsO_4 \cdot 1/2\,H_2O$ or $As_2O_5 \cdot 4\,H_2O$ crystallizes from arsenic acid solutions.

The highly poisonous arsenic hydride, AsH_3, is formed from arsenic compounds in acidic solution in the presence of strong reducing agents (e.g., Zn) or from suitable arsenides (e.g., As_2Zn_3) and acids.

1.4. Occurrence [1], [6–9]

Arsenic is widespread and can be detected in traces everywhere. With an abundance in the earth's crust of ca. $(2-10) \times 10^{-4}$ %, it is scarce but is found in higher concentrations in sulfide deposits (60 ppm or more). Worldwide most arsenic is produced as a byproduct of copper and lead smelting.

Native arsenic is found in many places, but only in small quantities, usually in ores containing gold, silver, cobalt, nickel, and antimony. Although many arsenic-bearing minerals are known, only a few occur in such quantities that they can be worked economically. The most important arsenic minerals are shown in Table 1. Other arsenides are chloanthite, $NiAs_2$; niccolite, NiAs; smaltite, $CoAs_2$; cobaltite, CoAsS; gersdorffite, NiAsS. Arsenic-bearing fahlores include inter alia tennantite, $4\,Cu_2S \cdot As_2S_3$; proustite, $3\,Ag_2S \cdot As_2S_3$. These minerals may be regarded as thioarsenites. Enargite, $3\,Cu_2S \cdot As_2S_5 = Cu_3AsS_4$, is a thioarsenate.

An extensive listing of all natural occurring arsenic minerals is given in [9].

1.5. Production

Most of the arsenic produced commercially accumulates as a byproduct in the smelting of nonferrous metal ores containing gold, silver, lead, copper, nickel, and cobalt. Today China is believed to be the only country that produces arsenic trioxide directly from arsenic ores [10].

Arsenopyrite often contains primary gold deposits. Fahlores and proustites always contain silver. Gersdorffite can accompany copper ores. Arsenopyrite and löllingite accompany pyrites [11]. Arsenic is mainly obtained from complex ores, such as enargite-containing copper, lead, and zinc ores. The arsenic content varies considerably.

Because of the volatility of arsenic sulfides and oxides, arsenic is mostly concentrated in the gas phase during roasting or smelting operations. A crude oxide is produced from the intermediate products, and, after refining, is reduced to the metal or is sold as is to the chemical industry for further treatment.

The falling world demand for arsenic oxide, the increasingly elaborate treatment of complex ores, the high toxicity, and environmental requirements have made arsenic-containing byproducts a problem for many producers. During the last decade research focussed on the stabilization of arsenic for safe disposal rather than on production technologies. In the early 1990s only China and Chile have countered the trend toward decreasing arsenic production [10]. Today arsenic is almost always an unwanted accompanying element in metallurgy.

1.5.1. Production of Arsenic Trioxide

History. Arsenic trioxide has been produced in China for 500 years in extremely simple plants, consisting of retorts with condensation chambers, from an ore containing 15 % As. However, it was not until the beginning of the 18th century that a smelter for native arsenic was set up in Germany at the instigation of J. v. SCHARFENBERG in Reichenstein, Silesia. Because the demand for As_2O_3 was relatively low, it was not until the 19th century that a second country, Great Britain, began producing As_2O_3. Thereafter, from the middle of the 19th century to 1901, Great Britain was the leading As_2O_3 producer. Production figures up to 1945 are only estimates. When legislation was introduced in various countries to avoid damage caused by release of As_2O_3-containing fumes, world production of As_2O_3 increased considerably. The production of native arsenic was given a fresh impetus by the appearance of the boll weevil in Mexico and the United States – damage from 1909 to 1923 was estimated at \$ 3 billion. Calcium arsenate was used to combat the boll weevil. The demand for arsenic became so great that it exceeded supply. New plants were established, particularly in the United States and Mexico. The largest plant was operated between 1932 and 1962 by Boliden AB in Rönnskär, Sweden.

Since the main use of arsenic trioxide as wood and plant preservative is declining (only the United States and developing countries such as Malaysia still allow the application of arsenic trioxide for this purpose), changes in the worldwide structure of arsenic trioxide production can be observed. While major producers of arsenic trioxide such as Boliden Mineral in

Sweden and Asarco in the United States ceased production, mostly for environmental reasons, China emerged as the world's largest producer of both arsenic trioxide and arsenic metal, selling both commodities to the United States [10].

1.5.1.1. Ore Dressing

The mining and dressing of ores with the primary object of recovering arsenic minerals are of little if any importance. Most arsenic raw materials are byproducts from the dressing and smelting of arsenical ores. The raw materials differ widely in character: mostly they are sulfides, often with pyrites as the principal constituent. For dressing, mixed arsenide – sulfide concentrates of very high metal content are floated, whereas the concentration of pure arsenic minerals is of secondary importance and should be avoided altogether [1].

The non ferrous metal concentrates used for the recovery of arsenic have arsenic contents from < 1 % to, in exceptional cases, 10 %. Table 2 shows As distributions in the concentrates and in the waste products, based on the initial As concentration in the ore [1].

In the concentration of complex ores, most of the arsenic remains in the tailings. In dressing tin ore, only 7.8 % of the arsenic passes into the tin concentrate. In the case of copper and copper – zinc ores, the arsenic is concentrated in the copper concentrate to a level of around 30 % of the quantity originally present in the starting ore. The copper concentrate therefore contains 0.5 – 1 % As, and concentrates of the complex ores up to 5 – 8 % As [1], [12].

One example of copper ore in which a large part of the copper is bound to arsenic, as enargite or luzonite, $3\,Cu_2S \cdot As_2S_5$, is the Lepanto ore from the Philippines. The flotation product contains approximately 28 % Cu, 32 % S, and 9 % As. In most ores, however, only a small proportion of the copper is bound chemically to arsenic, and the copper concentrates have a considerably lower arsenic content. Enargite-containing copper concentrates are produced in Cerro de Pasco (Peru) and Butte, Montana (USA) [1].

Arsenopyrite often occurs in pyritic copper ores, for example, on the Iberian Peninsula, in the Balkan countries, in Sweden, and in New Brunswick, Canada. The arsenopyrite can be recovered by selective flotation. Copper pyrites are removed by flotation with higher xanthates, the other sulfide minerals being held back by lime. After acidifying and heating the pulp, the pyrites and lastly, after further acidification and activation with copper sulfate, the arsenopyrite are flotated. Alternatively, after flotation of the copper pyrites, the arsenopyrite may be selectively floated from the pyrites pulp after heating and activation with copper sulfate.

In many precious metal ores, gold and silver occur together with arsenopyrite (FeAsS), löllingite ($FeAs_2$), and pyrites or other sulfides. Although the metals are not chemically bound to the arsenic, instead occurring as native gold and in the form of nonarsenical minerals, separation by selective flotation is not satisfactory on account of a partially extensive intergrowth of the minerals. In such a case, a combined concentrate of sulfides and arsenides with an arsenic content from a few percent to more than 30 % is floated. Research is still focussed on improving the separation of refractory gold and arsenical minerals by means of ore dressing, but in the case of refractory Au ores the limit of flotation and other classical ore dressing techniques has been reached [13], [14].

An example of the dressing of a combined precious metal and arsenic ore is the ore from Salsigne, France: an arsenopyrite – pyrites ore containing precious metals in large quantities, some copper, and a little bismuth. A description

Table 2. Distribution of arsenic in the production of the concentrated raw materials (% of arsenic content in starting ore) [12]

	Complex ores	Copper and copper – zinc ores	Tin ore	Gold-bearing ore	Nickel – cobalt-bearing ore

Others	–	–	–	–	1.9
Waste products	84.7	59.0	82.6	65.0	98.1

of the flotation circuit is given in [15]. The metal concentrate obtained contains ca. 23 % As, 27 % S, 34 % Fe, 0.7 % Cu, 0.6 % Bi, 55 ppm Au and 115 ppm Ag [1], [15].

Lead and copper concentrates rich in arsenic are produced in Mexico, South America, and South West Africa; cobalt concentrates in North Africa; and precious metal concentrates in Canada, South America, and other regions [1].

A trend in mining and minerals processing is to produce so called dirtier concentrates from complex ores. Therefore, the copper and zinc industries are forced to cope with concentrates which are higher in arsenic content. At the same time, new environmental laws mean increased effort and therefore costs for avoiding the distribution of arsenic in byproducts and for stabilizing it for save disposal. The tolerable As content of zinc concentrates for hydrometallurgical zinc recovery (about 80 – 85 % of the total primary zinc recovery) is limited to about 0.8 % [16–18].

Nickel concentrate at the Luikonlahti Concentrator of Partek in Finland has varying As contents of up to 5 % As. To transform such high-arsenic Ni concentrates into a saleable product, research was undertaken to separate pentlandite from As-containing niccolite and gerdorffite by advanced flotation with a combination of grinding, aeration, and NaCN depression [19].

Arsenic ores worth extracting and usable in concentrated or unconcentrated form as starting material for the production of arsenic seem to be processed only in China [10].

1.5.1.2. Pretreatment of Arsenical Materials

Arsenic in nonferrous metal smelter feed constitutes a major source of concern since it increases production costs, interferes with metal extraction, lowers product purity and quality (e.g. deformability), represents an environmental hazard, and poses disposal problems. Therefore, arsenic should be separated as early as possible, which is also dictated by industrial safety regulations. Especially in pyrometallurgical processes, the formation of arsenic-rich phases (speisses) in the reducing smelting of arsenic-rich raw materials leads to intolerable losses because of their ability to dissolve large quantities of precious metals [1], [8], [20].

Processes for the dearsenifying pretreatment of arsenical materials are therefore of great interest and increasing importance in the nonferrous metals industries. Among various pyro- and hydrometallurgical options, dearsenifying roasting is quite widely used. For certain applications, hydrometallurgical processes such as oxidative pressure leaching or biochemical pretreatment are applicable alternatives.

1.5.1.2.1. Roasting

The separation of arsenic by roasting is complicated by the multivalency of arsenic, i.e., its ability to form more than one compound or complex with a given element. Arsenic in arsenopyrite can be transferred to the vapor phase as any of its volatile compounds: As_4S_4, As_2S_3, AsS, As_4O_6, As_4, As_2, etc. Besides $AsCl_3$, As_4O_6 possesses by far the highest vapor pressure. However, which compound will be predominant depends on the prevailing partial pressures of oxygen and sulfur.

The final product should contain so little arsenic that it can be further treated as a quasi-arsenic-free material. To obtain a high arsenic

removal rate and hence a high concentration of arsenic in as few processing steps as possible, the roasting process must be conducted such that only volatile arsenic compounds or As_4 or As_2 form. The formation of nonvolatile arsenic compounds such as As_2O_5 or arsenates, which remain in the roasted material, must be avoided. The valuable metals remain in the roasted material as sulfide or oxide, depending on the process conditions [1], [8], [21–23].

Although predominance area diagrams represent equilibrium conditions, they can be used to evaluate roasting phenomena. Figure 1 shows three faces of the quaternary system Fe – As – S – O at 798 K. The diagram reveals that the partial pressures of O_2, S_2, and As_4 are each limited by the precipitation of a condensed phase. The partial pressure of O_2 in the Fe – As – O system is limited by the reaction between As_4 and O_2 in the production of the solid pentoxide [22].

Figure 1. Predominance area diagram for the Fe – As – S – O system at 798 K [22]

Reviews of the roasting conditions reveal that inert, reducing, and oxidizing conditions can be used to eliminate arsenic from arsenical materials. To separate As from concentrates, oxidizing conditions appear to be the most promising. In this case, higher temperatures and higher oxygen partial pressures lead to the stability area of As_4O_6. Above a certain temperature that depends on the oxygen partial pressure, nonvolatile As_2O_5 and metal arsenates, which decompose only at high temperatures, become stable, and this leads to a poor yield of As in the flue dust. Higher As contents in the raw material result in a better dearsenification, and higher SO_2 partial pressures expand the stability field of As_4O_6 [8], [21–23].

At high SO_2 partial pressures, i.e., at low O_2 partial pressure in the roasting zone, volatile arsenic oxides are mainly formed:

$$4\,MAs + 5\,O_2 \longrightarrow 4\,MO + 2\,As_2O_3$$

At higher O_2 partial pressures the overall course of the reaction may be written as:

$$MAs + 2\,O_2 \longrightarrow MAsO_4$$

As_2S_2 and As_2S_3 are volatile at low temperatures. Arsenopyrite and similar compounds decompose:

$$FeAsS \longrightarrow FeS + As$$

At low oxygen partial pressure, particularly in the case of pyrites-containing materials, the sulfur partial pressure reaches such high levels that reactions of the following type attain practical significance in the gas phase:

$$2\,S_2 + As_4 \longrightarrow As_4S_4$$

$$As_4S_4 + 7\,O_2 \longrightarrow (As_2O_3)_2 + 4\,SO_2$$

In the dearsenifying roasting of raw materials containing arsenopyrite or other dissociable substances, the dissociation reaction and secondary reactions are important factors. The best results are obtained by roasting at low oxygen partial pressure. To convert all the arsenic into the trioxide, the oxidation of the dissociation products has to be completed at a relatively high oxygen partial pressure. Before cooling and purification, therefore, the roasting furnace gases are burnt under controlled conditions. If only partial desulfurization is necessary, a single-stage process is sufficient. For complete desulfurization, however, a two-stage process may be necessary [1].

If roasting is correctly controlled, arsenic can be separated in high yields from the most important arsenic minerals, namely arsenopyrite, FeAsS; löllingite, $FeAs_2$; and enargite,

$3Cu_2S \cdot As_2S_5$. Nickel and cobalt arsenide minerals are much more stable and therefore more difficult to roast. Fahlores and proustite are also very stable [1].

The following roasting processes are in use [8]:

- Partial roasting: Here the calcine still contains FeS, and there is no tendency for formation of stable metal arsenates. Arsenic elimination depends on the retention time. Multiple-hearth and single-stage fluidized-bed roasting are applicable.
- Magnetite roasting: In this case the calcine is in the Fe_3O_4 form, and arsenic elimination is satisfactory. The Boliden process is based on one-stage fluidized-bed roasting to magnetite.
- Dead roasting: The calcine is principally in the Fe_2O_3 form with residual sulfur. Arsenic can be eliminated by multiple-hearth roasting or two-stage fluidized-bed roasting, as in the BASF process.
- Reducing roasting: To prevent formation of iron(III) arsenate, roasting is sometimes carried out under reducing conditions, especially if the required degree of sulfur elimination is high, as in the dearsenicating roasting of complex tin concentrates. It has also been applied in the partial roasting of copper concentrates to obtain low residual As levels.
- Sulfidizing roasting: In the sulfidizing evaporation pretreatment process of Outokumpu, it was proposed to operate in the p_{S_2} range of 0.05 – 0.1 bar at 600 – 800 °C , which would result in 0.1 % As in the calcine, independently of the degree of desulfurization.

Roasting Plants. Any standard roasting furnace (multiple-hearth or fluidized-bed furnace, sintering apparatus or cyclone) may be used for roasting arsenical raw materials. Multiple-hearth furnaces and fluidized bed reactors are the most common aggregates for industrial dearsenifying roasting processes. Details of the roasting technology and a review of industrial applications are provided in [8], [22], [24].

Multiple-Hearth Furnaces. Where roasting is carried out in a multiple-hearth furnace (e.g., a Wedge furnace), the atmosphere in the material bed during the first part of the roasting process should be sufficiently low in oxygen to prevent formation of arsenates. In this region most of the arsenic compounds are released from the material being roasted and are then oxidized in the atmosphere richer in oxygen over the bed of material being roasted before dust separation and cooling. Before it is discharged, the roasted material encounters the oxygen-rich fresh gas through the quantity of which the sulfur content can be adjusted to the required level. On account of the long residence time, mass diffusion is not a problem, even in relatively large particles. However, the maximum temperatures have to be limited to avoid melting and contamination. Multiple-hearth furnaces operate under reduced pressure. The flue dust content of the off-gases is relatively low.

Fluidized-Bed Furnaces. Because of their high roasting capacity, low maintenance costs, and the high content of SO_2 in the off-gas, fluidized-bed roasters are increasingly being used for the roasting of sulfidic raw materials. In applications with the aim of a partial roasting procedure, e.g. for the subsequent matte smelting in the primary copper industry, multiple-hearth furnaces are still in use to about the same extent as fluidized-bed furnaces. Especially for the dead roasting of arsenical materials, where the major aim is to remove sulfur rather than arsenic, fluidized bed roasters are being increasingly preferred to multiple-hearth furnaces. Table 3 gives some details on industrial fluidized-bed roasting plants.

In fluidized-bed roasting, temperature and gas composition are easily kept constant at a level favoring separation of arsenic and subsequent complete desulfurization. The composition of the mineral, the arsenic content, and the grain size of the raw material are critical factors affecting the efficiency of arsenic separation during roasting. The roasted material is completely or partly transported with the off-gases to the gas-cleaning system, which makes gas cleaning difficult. During cooling of the gas, the arsenic trioxide can react with the metal oxides, so that the roasted material must be mechanically separated at elevated temperature. Even after this has been done, the gas still has a high flue dust content, which affects the separation of As_2O_3 and necessitates the installation of equipment for selective gas cleaning if the highest possible As_2O_3 content is to be obtained in the product.

Off-Gas Cleaning (Separation of Arsenic from Arsenic-Bearing Gases). The gas-cleaning system must provide the possibility to collect the

dust carry-over and the volatized arsenic separately. Because of the aim to gain a high concentration of arsenic in the product and the tendency of arsenic to react with with metal oxides under oxidizing conditions in the off-gas stream to form metal arsenates, off-gas cleaning is a critical unit operation in dearsenifying roasting processes.

The waste gases from the roasting reactors may first be burnt. They are then freed from dust in, for instance, a hot cyclone and a hot electrostatic precipitator above the condensation temperature of As_2O_3. To achieve sufficiently low levels of arsenic (1 mg/m^3) for use of the SO_2 in a sulfuric acid plant and to prevent the formation of metal arsenates, the oxygen potential should be as low and the temperature as high as possible in the primary gas cleaning step. The gases are then subsequently cooled to about 100 °C . Relatively pure As_2O_3 is deposited in bag filters.

Wet cleaning systems such as wet scrubbers, ionizing washers, and wet electrostatic precipitators may also be applied. In the wet gas cleaning systems, arsenic is washed out and eventually dissolves in the acidic solution [1], [8].

Arsenopyrite. For the roasting of arsenopyrite with the aim of arsenic recovery the roasting plant which was run by Boliden AB at Rönnskär is a good example, although production ceased in 1991 [10]. The multiple-bed furnace contained 9 – 11 hearths with a total hearth area of 230 m^2. The maximum roasting temperature was 500 – 800 °C . Most of the arsenic was removed in the upper hearths. Arsenic and arsenic sulfides were then allowed to burn in the roasting gas. After passing through a cyclone and a flue-dust filter, the roasted material was cooled in a metal air cooler to below the condensation temperature of As_2O_3 and purified in a hot precipitator with an exit temperature of 120 – 140 °C . Sulfuric acid was recovered from the gas containing 3 – 5 % SO_2 in a fine purification plant (washing tower or wet electrostatic precipitator). In the roasting of concentrates containing 12 %

As, the crude oxide that accumulated in the air cooler and the hot precipitator had an As_2O_3 content of 80 – 95 %. The arsenic content was lowered from 11 % in the arsenic concentrate to 1.37 % in the calcine [1], [25].

At Salsigne, France, a multiple-hearth furnace with 12 hearths and an inner diameter of 4 m was used to reduce the arsenic content from 32 % in the concentrate to 0.5 % in the calcine [15].

In the former Soviet Union an arsenopyrite/pyrites concentrate from Darunskii containing 9 – 13 % As and 32 – 40 % S is partially roasted at ca. 575 °C in a fluidized-bed furnace. After the roasting gas has been cleaned in a hot cyclone and a hot electrostatic precipitator (400 °C), the oxide is separated in a condensation chamber. The roasted material contains ca. 0.5 % As and 12 % S; the oxide has a purity of 92 – 97 % [1].

Arsenic-Containing Gold Concentrates. Refractory gold ores are characterized by poor metal extraction in direct cyanidation. Their refractory nature may be due to the presence of carbon and/or locking of gold and silver in arsenical and other sulfide minerals. Sulfidic arseniferrous gold ores exist in many parts of the world: in Canada (Giant Yellowknife, Campbell Red Lake), in the former Soviet Union (Darasun), in South Africa (Barberton Area in Eastern Transvaal, New Consort Mine), France (Salsigne), Greece (Olympias), Brazil (Sao Bento). Roasting of refractory gold concentrates has the objective to render the gold amenable to leaching. The roasting process should achieve:

1) The decomposition of arsenopyryite or enargite to produce hematite or copper sulfide, respectively, and fixation of arsenic as arsenic trioxide and/or iron arsenate
2) The fixation of sulfur values as sulfuric acid or as gypsum by scrubbing the sulfur dioxide and other gases

With arsenopyrite ores and concentrates, two-stage roasting in fluidized bed roasters has been practised on a commercial scale at Campbell Red Lake, Giant Yellow Knife, and New Consort Mine. During the first-stage roasting at 500 °C, arsenic elimination of ca. 65 – 70 % and pyrite conversions of 20 – 30 % are common. Arsenic is collected as arsenic trioxide. Air ratios are 60 – 80 % of the stoichiometric requirement. The second stage is carried out at slightly higher temperature of 530 °C with about 10 % excess air. Arsenic elimination in the final calcine is in the 90 – 95 % range, and sulfur removal in the 85 – 90 % (Table 14).

A number of different roasting technologies vary this two-stage scheme by fixing a large part of the arsenic as iron arsenate instead of As_2O_3 (METBA process); by applying a multiple-hearth furnace for the first stage (Mechim process); by roasting at higher temperatures (800 – 850 °C) in the first stage and thus oxidizing the pyrite to pyrrhotite or magnetite, which is further oxidized to hematite in the second stage (Boliden process and BASF process); and by extending the roasting process to a third stage (Montedison process) [8], [15], [23], [24], [26], [27], [28].

Arsenic-Containing Copper Concentrates. Copper smelters are the biggest producers of arsenic-containing intermediate products. The arsenic content of copper concentrates varies over a wide range, in many cases reaching 1 – 10 %. Pretreatment of copper concentrates by partial roasting to remove arsenic and adjust the sulfur content has long been applied commercially. Nowadays it has been replaced in many cases by the Outokumpu flash smelting furnace, in which the concentrate is roasted and the matte smelted at the same time (see Section 1.6). Usually the copper concentrate is roasted in multiple-hearth furnaces, and the process is controlled such that optimal conditions for removal of arsenic prevail in the upper hearths, whereas in the lower hearths the sulfur content of the material being roasted is reduced to the level required for the subsequent smelting of low-grade matte (e.g., 15 – 20 %).

The processes and plants used are much like those used for the roasting of arsenopyrite (see above). Roasting is exothermic, and the maximum roasting temperature can reach 500 – 800 °C, depending on the composition of the batch. The yield of arsenic also depends on the composition of the batch, the type and quantity of the arsenic minerals, the roasting temperature, and other factors. For high arsenic contents or when arsenopyrite or enargite are present, the yield can be more than 80 %. For lower arsenic contents the yield can be much lower because a

few tenths of a percent of arsenic always remain in the roasted material.

After the hot roasting gas has been cleaned in cyclones and dust-settling chambers, relatively small quantities of a crude arsenic heavily contaminated by flue dust and volatile substances are obtained by cooling the off-gas. The As_2O_3 content of the product is generally between 10 and 50 %. However, far higher contents can be obtained by using electric precipitators to remove dust from the hot gas. The dust left after cleaning of the hot gas is returned to the process.

The cleaned SO_2-containing gas still contains traces of arsenic and other impurities that have to be removed by washing with water or a circulating washing liquid containing sulfuric acid and by final cleaning in a wet electric precipitator. The sulfur is used to produce sulfuric acid. The arsenic-containing slurries that accumulate during wet cleaning and effluent treatment are collected and neutralized to recover valuable materials.

Examples for the partial roasting of copper concentrates are St. Joe's El Indio Mine, Chile [29], [30] (multiple-hearth roasting) and the roasting of Lepanto concentrates at Pasar, Philippines (fluidized-bed roasting).

Arsenic-Containing Pyrites Concentrates. Pyrites are roasted to generate sulfur dioxide for the production of sulfuric acid (→ Sulfur Dioxide, Chap. 5.). The roating residue, known as pyrite cinders, contains most of the impurities which were initially present in the pyrites. The composition of pyrites can vary over a wide range: Fe 42 – 49 %, S 45 – 52 %, As 0.05 – 0.4 %, Sb 0.01 – 0.05 %, Zn 0.2 – 4 %, Pb 0.1 – 1.5 %, Cu 0.04 – 1.5 %, Ag 10 – 60 ppm, Au 0.5 – 2 ppm.

The production of sulfuric acid implies the subsequent treatment of the pyrite cinders, since their impoundment is becoming more and more problematical. To convert pyrite cinders to iron ore the nonferrous metals must be removed to a large extent. The maximum levels of impurities tolerated in iron ore are S $\leq$ 0.5 %, As $\leq$ 0.05 %, Cu $\leq$ 0.1 %, Zn $\leq$ 0.1 %, Pb $\leq$ 0.02 % [8].

During cinders treatment there are no commercial facilities for the elimination of arsenic. It therefore has to be separated from the iron in the primary pyrite roasting stage. The roasting process must be conducted in such a way that as much arsenic as possible is removed. In addition the gas must be freed from arsenic completely before it is delivered to the sulfuric acid factory or otherwise used. Besides arsenic compounds, other constituents, such as selenium or mercury may be obtained at the same time.

The traditional process for the dearsenicating roasting of pyrites is multiple-bed roasting controlled so that the arsenic is released in the low-oxygen atmosphere of the upper beds, whereas the sulfur is released in the oxygen-rich atmosphere of the lower beds. The gases formed have a relatively low SO_2 content and such a high oxygen content that arsenic, sulfur, and the arsenic sulfides are completely oxidized. The As_2O_3 formed reacts further with Fe_2O_3 and oxygen to form iron arsenate. Therefore, most of the arsenic in the dust is in bound form and, in addition, because of the low total content, is an unsuitable starting material for arsenic. The multiple-bed roasting of pyrites has largely been replaced by fluidized-bed roasting.

The standard process for roasting pyrites in a fluidized bed forms Fe_2O_3 with excess air. This is unsuitable for roasting arsenic-bearing ores because the arsenic then is bound as iron arsenate in the roasted material. Two fundamentally different processes have been developed for the fluidized-bed roasting of arsenic-bearing pyrites: the two-stage BASF process and the single-stage Boliden process.

In the two-stage process developed by BASF, about one-half of the sulfur present is roasted off in the first reactor at around 900 °C at a low oxygen partial pressure. After solids and gas have been separated in a cyclone, roasting is completed in a second reactor around 800 °C in excess air. Air is added to the gas stream of the first reactor to burn the sulfides and other volatile substances still present. The gas is then cooled in a waste-heat boiler and cleaned in a hot precipitator and by washing. Some of the arsenic is present as iron arsenate in the dust precipitated, and some is washed out as As_2O_3 during wet cleaning [26], [31].

In the single-stage fluidized-bed roasting process developed by Boliden AB at Reymersholm, the pyrites are roasted in such a way that magnetite, Fe_3O_4, is formed from the iron in the ore at a low oxygen partial pressure. In contrast to Fe_2O_3, magnetite does not react with the As_2O_3 to form arsenate. A small amount of

iron arsenate is separated with the flue dust. The gas freed from the flue dust is mixed with air to burn the dissociation products. Then it is cooled in a waste-heat boiler, freed from dust in a hot precipitator, and subjected to wet gas cleaning which separates most of the arsenic as As_2O_3 [32], [33].

In the wet cleaning of the roasting gases, the gases are washed with water or circulating sulfuric acid solutions in washing towers, Venturi scrubbers, or other apparatus and finally are cleaned in wet precipitators. Separation of the arsenic by the wash liquid is almost complete, although neutralization, utilization, or storage of the arsenic removed presents problems. Normally the process water is circulated so that a high concentration of dissolved substances builds up; a side stream is purified. For example, the arsenic may be precipitated with lime, possibly after neutralization with alkalis. Because the wash liquids are strongly acidic and contain many impurities, the consumption of chemicals is high and the product impure. Selective precipitation may be carried out. At the Reymersholm works of Boliden AB, the As_2O_3 is continuously recovered from the circulating sulfuric acid wash solution by crystallization. The product obtained serves as raw material for the production of refined As_2O_3.

Other Arsenic Containing Concentrates and Materials. Besides the above arsenic-containing concentrates and ores, dearsenicating roasting is applied to a wide variety of nonferrous metal concentrates such as complex tin concentrates, cobalt arsenides, and lead or zinc concentrates. Roasting can also be used for the separation of arsenic from intermediate products from various smelting processes, e.g., tin-bearing speiss which was generated in the blast furnace smelting of Pb/Cu primary material at MHO [8], [34].

1.5.1.2.2. Alternative Pretreatments of Arsenical Materials

Apart from the well-known, classical roasting processes for the dearsenification of ores, concentrates, and arsenic-containing intermediate products, recently the focus has shifted more to hydrometallurgical alternatives. One possible reason is the lower number of product phases compared to pyrometallurgical operations and therefore better selectivity. Furthermore, the arsenic-containing products of most hydrometallurgical operations are relatively stable arsenic compounds, such as ferric arsenates, which are suitable for dumping. Given the rapidly shrinking market for As_2O_3 and the limited applications of arsenic metal, the separation of arsenic in combination with its stabilization is of increasing economical interest in many industrial applications.

Hydrometallurgical pretreatment technology is quite common in the recovery of gold from refractory gold ores. For copper concentrates, two processes based on sodium sulfide leaching have been described, one of which was operated at Equity Silver Mines. Their economical and industrial importance seems to be minor.

Hydrometallurgical Pretreatment of Refractory Gold Ores. Hydrometallurgical pretreatment of refractory gold ores or concentrates consists of an oxidative treatment to oxidize the sulfides, mainly pyrites and arsenopyrites, to sulfates. Thus, the formerly enclosed gold is made amenable to subsequent leaching.

Oxidative Pressure Leaching. The oxidative pressure leaching of refractory gold ores operates at 160 – 180 °C, a pressure of 1300 kPa and 40 – 45 % solids in the feed pulp (Fig. 2). The required retention time is 1.5 – 2 h and oxygen consumption 0.1 t per tonne of ore. The final acidity is 15 – 20 g/L H_2SO_4. More than 95 % of the sulfur is oxidised to sulfate, and iron and arsenic are precipitated according to the following simplified reaction equations:

$$FeS_2 + 15/4\,O_2 + 2H_2O \longrightarrow 1/2\,Fe_2O_3 + 2\,H_2SO_4$$

$$FeAsS + 11/4\,O_2 + 1/2\,H_2O \longrightarrow FeAsO_4 + 1/2\,H_2SO_4$$

The oxidative pressure leach may be preceded by a pre-leaching stage. After oxidation and subsequent solid – liquid separation, the gold can be recovered from the solids by cyanidation, while the solution is neutralized with limestone and the precipitate is dumped as tailings.

Figure 2. Flowsheet for oxidative pressure leaching of refractory gold feedstocks [35]

In Canada miniplant campaigns have been performed at the Sherrit Research Centre on various arseniferrous gold ores such as Campbell Red Lake, Giant Yellowknife, and Olympias, and have been translated to commercial plants at Key Lake and Sao Bento [8], [35].

A silver-rich copper concentrate containing 17 % Cu, 7000 g/t Ag, 19 g/t Au, 8 % Sb and 3 % As is treated as illustrated in Figure 3. At the heart of the process are two autoclaves for the removal of Sb and As. The arsenic is converted by treatment with CaO into insoluble Ca_3AsO_4. The production of calcium arsenate requires O_2 pressures of 1.5 MPa and a temperature of 190 °C . The calcium arsenate crystals are centrifuged off and dehydrated in a filter press. Production capacity is 600 t/a of calcium arsenate [36].

Biochemical Pretreatment. For the selective biochemical oxidation of gold ores the most widely used bacterium is *Thiobacillus ferrooxidans*, which oxidizes reduced sulfur compounds, such as mineral sulfides, and reduced iron to obtain energy for growth and other life processes. These bacteria, which thrive in acidic conditions, break down sulfide minerals, release metal into solution and, if pyrite is present, increase the acidity of the solution. For refractory ores, oxidation of the gold-bearing sulfides liberates the gold from the mineral matrix and makes it available for recovery (see also → Liquid – Solid Extraction, Chap. 3.3.3.).

Among many chemical reactions involved in the action of *T. ferrooxidans*, the reactions of pyrite are summarized in the following:

$$4\,FeS_2 + 14\,O_2 + 4\,H_2O \longrightarrow 4\,FeSO_4 + 4\,H_2SO_4$$

$$4\,FeSO_4 + O_2 + 2\,H_2SO_4 \longrightarrow 2\,Fe_2(SO_4)_3 + 2\,H_2O$$

$$FeS_2 + Fe_2(SO_4)_3 \longrightarrow 3\,FeSO_4 + 2\,S$$

$$2\,S + 2\,H_2O + 3\,O_2 \longrightarrow 2\,H_2SO_4$$

The oxidation of arsenopyrite can be represented by the following reaction in which pentavalent arsenic (arsenic acid) is formed:

$$4\,FeAsS + 13\,O_2 + 6\,H_2O \longrightarrow 4\,H_3AsO_4 + 4\,FeSO_4$$

Trivalent arsenic (arsenous acid) may be formed as an intermediate product, followed by oxidation of trivalent arsenic to the pentavalent form by iron(III). In the presence of iron(III) in solution, ferric arsenate may be formed from arsenic acid and precipitate.

A process for treating a refractory arsenical gold concentrate was operated on a commercial scale (2 t/d) in a pilot plant at Equity Silver Mines, British Columbia in 1984/1985 with recovery of gold in a cyanide circuit. Small commercial plants are reportedly in operation in South Africa and Zimbabwe [37].

Direct Hydrometallurgical Treatment of Arsenical Concentrates. A number of processes for the direct hydrometallurgical treatment of other concentrates and ores have been developed. These include Co – As concentrates as well as complex Cu – Co – As concentrates and Ni – As concentrates, which are treated by pressure oxidation or atmospheric leaching with HNO_3 oxidation, respectively. The Nitrox process was developed for the hydrometallurgical treatment of refractory gold concentrates and ores. It consists of a direct oxidation with nitric acid at atmospheric pressure and a temperature of 85 °C [8], [38–40].

1.5.1.3. Production of Refined As_2O_3

Preliminary Concentration [1]**.** The starting material for the industrial production of refined As_2O_3 is the arsenic-rich dust or slurry that accumulates as an intermediate product in the roasting and smelting of arsenic-bearing ores and concentrates. The bulk of this arsenic raw material comes from copper smelters, although some also comes from lead, cobalt, and

Figure 3. Simplified schematic flow sheet of leach plant at Equity Silver Mines, British Columbia

other smelters. Occasionally, in the former Soviet Union and possibly China, arsenic-rich ore is roasted with the primary object of recovering arsenic. All these raw materials of various origins and arsenic contents have in common that they are obtained as products of gas cleaning and also contain other condensation products and flue dusts. Arsenic is mainly present as As_2O_3, although some may also be bound as arsenite or arsenate. The arsenic content can vary enormously, depending on the ore used and the way in which roasting and gas cleaning are carried out. The gas-cleaning products often contain other valuable constituents and, because of this, must be worked up even if the arsenic content is very low. In such cases the materials are circulated until the arsenic content exceeds 10 %. Low-grade gas-cleaning products of low As_2O_3 content from copper and lead roasting plants contain flue dust from the furnace charge as their principal impurity, whereas the high-grade products mainly contain volatile impurities, such as lead, antimony, bismuth, and selenium. Most of the impurities are present as oxide or sulfate.

Low-grade starting materials are treated in a multistage process. In the first stage the material is roasted to produce ≥ 80 % As_2O_3. This is sublimed and separated from the roasting gases. The bulk of the impurities remains in the roasted material, which is returned to the original process or treated separately to recover valuable secondary products. To increase the yield of arsenic and to facilitate the movement of material through the roasting furnace, sulfides or charcoal are added as reducing agents to the furnace charge. The reducing atmosphere thus established in the material decomposes the metal arsenates and no more arsenate is formed. For example, dust from the gas-cleaning process is mixed with a few percent of iron pyrites concentrate, and the resulting mixture heated at 300 – 500 °C in oil-fired multiple-hearth furnaces. The arsenic-containing gas is cooled in a long brick pipe, passes through a flue-dust chamber, and then through several chambers in which the temperature falls from 220 °C to below 100 °C to separate the arsenic. Finally the gas is cleaned in bag filters. In this system the flue dust and gaseous impurities of low vapor pressure are separated preferably in the first part of the system, so that the gas-cleaning process is fractionated. In a critical temperature range above 200 °C, a relatively small quantity of impure, amorphous glassy ar-

senic trioxide accumulates. However, most of the arsenic trioxide obtained is crystalline. A product containing the high vapor pressure impurities is separated in the bag filter.

Some of the crude arsenic from the separating chambers containing more than 95 % As_2O_3 is sold, but most of it is refined further. The less pure products are returned to the process.

Refining. High-purity crude oxide, obtained either directly or via concentration processes, can be dry refined by sublimation or wet refined by dissolution and crystallization.

The widely used sublimation process is carried out by heating the crude arsenic in a reverberatory furnace. The gases are passed through a dust-settling chamber to a ca. 70-m-long system of, e.g., 39 brick arsenic separation chambers called kitchens. The kitchens are followed by a bag filter. The temperature in the dust-settling chamber is kept at ca. 295 °C, which is considerably above the condensation temperature of arsenic trioxide. The temperature of the bag filter is kept at 90 – 100 °C. A black, amorphous arsenic trioxide containing ca. 95 % As_2O_3 accumulates in the first kitchens. In the following kitchens, in the temperature range from 180 to 120 °C, most of the arsenic trioxide accumulates in a crystalline form analyzing more than 99 %. The product separated in the last kitchens below 120 °C and in the bag filters assays ca. 90 % As_2O_3. The low-purity products are returned to the process or, if they assay more than 95 % As_2O_3, are sold as crude arsenic. The high-purity products from the middle kitchens are marketed as white arsenic.

Several versions of the dry refining process, e.g., with repeated sublimation, have been described in the literature. The Rönnskär works have developed a process for the production of nondusting white arsenic by shock cooling of hot-cleaned sublimation gas [41].

The wet refining of crude oxide is based on the large temperature coefficient of the solubility of As_2O_3 in water (12.1 g/L at 0 °C, 18.1 g/L at 20 °C, 81.8 g/L at 98.5 °C), on the low solubility of the impurities, and on the the purification accompanying crystallization of the As_2O_3.

In the wet refining process, introduced at Rönnskär works as early as 1930, the crude oxide, assaying from 80 to 90 % As_2O_3, is brought in a closed system to the refining plant and pressure leached in steam-heated autoclaves with water or circulating solution. The As_2O_3 dissolves, whereas the impurities, such as oxides, sulfides, sulfates, and arsenates of lead, bismuth, antimony, iron, and other metals, as well as silica, selenium, and other substances, form a slightly soluble sludge, which is separated from the hot leaching solution. The solution is vacuum cooled, and the crystallization is controlled to give a relatively coarse product, which is separated by centrifuging from the solution, washed, dried, and packaged in a closed system. The mother liquor is recycled. The process is fully continuous and also satisfies stringent industrial hygiene requirements. The wet-refined arsenic contains more than 99 % As_2O_3 and is marketed as white arsenic, either in metal casks or in lined wooden casks.

At Nerco Con Mine in Canada, dumping ponds containing over 70 000 t of sludge from off-gas cleaning of the former roasting operation had to be treated for environmental reasons. The sludge contains 50 % arsenic trioxide, 0.70 tr oz/t gold and 1.20 tr oz/t silver. The material is extremely difficult to handle. It is toxic, very fine, with an average particle size of 85 % $< 5\,\mu m$, and forms a thixotropic mass containing 35 % moisture. The arsenic is extracted in a two-stage countercurrent leach at 95 °C. In the primary stage, 90 % of the available arsenic trioxide is extracted, and the remainder in the secondary stage. Key process developments are the addition of small amounts of hydrogen peroxide to enhance the rate of leaching, and clarification by thickening and filtration through powdered activated carbon. The hot pregnant liquor is subjected to four stages of evaporative cooling and crystallization. The plant at Nerco Con Mine was shut down in 1985 and reopened in 1987 with a newly developed carbon filtration system [42].

1.5.2. Production of the Metal

Arsenic metalis produced on a fairly wide scale as commercial arsenic metal, primarily as an additive for alloys, and to a lesser extent as high-purity arsenic for electronic applications.

Commercial-Grade Arsenic Metal [1]. The starting material for the production of commercial-grade arsenic metal is usually white

arsenic. However, the metal can also be produced from arsenopyrite or löllingite.

In the processing of As_2O_3 the oxide is normally reduced with carbon:

$$2\,As_2O_3 + 3\,C \longrightarrow As_4 + 3\,CO_2$$

The reaction is endothermic and is carried out at 500 – 800 °C. The elemental arsenic sublimes and is condensed out of the reaction gas by cooling.

There are several versions of the carbon reduction process. In one version a mixture of As_2O_3 with 25 % charcoal is placed in a horizontal steel retort jacketed with firebrick and heated to 650 – 700 °C in a gas-fired furnace. The reaction gas is collected in water-cooled condensers, in which the metal separates as crystals. After about 10 h, the heating is stopped, and, after the furnace has cooled, the metal can be removed from the condensers.

Similar processes are thought to have been used by several producers. For example, at the Rönnskär works of Boliden AB, steel retorts are provided with demountable air-cooled condensers. After the cold retorts have been charged, they are closed and heated to 700 – 800 °C in an electric furnace. The metal is separated in the condenser, while the off-gases are cleaned in a scrubber system. Most of the metal is coarsely crystalline. After size reduction and grading, the arsenic is packaged in metal casks. In the process used at the Reichenstein works in Silesia, As_2O_3 was vaporized by indirect heating in a gas-heated retort furnace, and the vapor was passed through a 3-m-tall incandescent coke layer into a tower reactor in which it was reduced to gaseous arsenic. The metal was separated in large condensers arranged in series.

Carbon monoxide [43] or ammonia [44] may also be used as reducing agents. Metallic arsenic may be obtained from arsenopyrite or löllingite by thermal dissociation:

$$4\,FeAsS \longrightarrow 4\,FeS + As_4$$

$$4\,FeAs_2 \longrightarrow 4\,FeAs + As_4$$

V. G. Rchiladze [45] described the theory of this process in detail and suggested how it may be carried out in practice. Arsenopyrite is placed in steel retorts lined with diabase or basalt and heated electrically in two stages to 700 – 900 °C. This causes the arsenic and a small quantity of sulfur compounds to volatilize. The metal vapor is condensed at 450 – 500 °C in an electrically heated steel condenser. The metal is scraped off the condenser walls and cooled in a closed system. The volatile sulfur compounds are separated from the off-gas at a lower temperature. The purity of the metal depends on the ore, specifically on the content of volatile impurities that condense under the same conditions as the arsenic. Some sulfur content is always present. In an experiment, metal containing more than 99 % As was obtained from arsenopyrite assaying from 25 to 45 % As. The principal impurities were sulfur and bismuth.

Practical experience in the production of metallic arsenic by reduction with carbon has shown that there are many difficulties. The danger to personnel and the risk of explosion are the two most important. In addition, As vapor is highly corrosive, so that the useful life of the plant is shortened significantly [46]. To overcome these problems, attempts are being made to produce metallic arsenic in other ways. Crystallized As can be obtained from $AsCl_3$, As_2S_3, or As_2O_3 by gas-phase reduction with hydrogen. The hydrogen required for reduction is produced in situ by the thermal dissociation of ammonia. The reduction is highly exothermic. This process is said to give an arsenic yield of 93 – 98 %. The off-gas contains 70 % N_2 and 30 % hydrogen. An advantage lies in a certain degree of refining that takes place. Table 4 shows one example of how impurities present in As_2O_3 affect the purity of the metallic arsenic. Figure 4 shows a schematic diagram for one such plant.

Table 4. Refining effect in the reduction of As_2O_3 with H_2

	As_2O_3, ppm	As, ppm

Figure 5. Flow sheet of the Cominco recovery process

Figure 6. Flow sheet for the production of high-purity arsenic metal at Sumitomo Metal Mining Corporation [51]

Another way of obtaining metallic arsenic is to sublime a Pb – As – Sb alloy to give 99 % pure arsenic metal. Flue dust containing antimony and arsenic and a lead-containing residue from the electrolytic refining of Pb are reduced with carbon to a lead alloy containing 7 – 12 % As and 18 – 30 % Sb. A 90 % As containing 10 % Sb and 0.05 % Cd is produced in a first vacuum distillation stage carried out at 480 – 590 °C (Fig. 5).

A 99 % As suitable for the commercial market is obtained in a second vacuum distillation stage carried out after removal of the cadmium from the residue [47].

Commercial arsenic produced from As_2O_3 contains > 99 % As and as its main impurities antimony and oxygen. This quality is used primarily for the production of alloys.

High-Purity Arsenic. Arsenic is produced in various high-purity grades for special applications. A limited refining effect can be obtained by resubliming commercial metal in a stream of hydrogen. In general, however, various purification stages are combined in the production of high-purity metal.

Figure 7. Material flow in the production of semiconductor-purity arsenic by the chloride method

Commercial arsenic is sublimed, reacted with oxygen to produce As_2O_3 which is recrystallized from aqueous hydrochloric acid, sublimed in a stream of hydrogen, and then reduced to the metal with hydrogen at 800 – 850 °C. The arsenic obtained has a purity > 99.999 % [48].

The process most often reported in the literature treats white arsenic with hydrochloric acid to form arsenic trichloride:

$$As_2O_3 + 6\,HCl \longrightarrow 2\,AsCl_3 + 3\,H_2O$$

The arsenic trichloride is purified by fractional distillation, possibly in combination with chemical methods. It subsequently is reduced by reaction with hydrogen at 800 – 850 °C, and the metal vapor is condensed in crystalline form at 400 – 450 °C.

$$4\,AsCl_3 + 6\,H_2 \longrightarrow As_4 + 6\,HCl$$

After sublimation, the metal is packaged in glass ampoules. An arsenic content of > 99.99 % can be obtained by this method.

Figure 6 shows the flow sheet for the production of high-purity arsenic at Sumitomo Metal Mining Corporation, and Figure 7 shows the distribution of arsenic in the process. The yield is 62 %. Table 5 lists the impurities present in the high purity arsenic after the individual process steps [1], [48–50], [51].

1.6. Treatment of Arsenic-Containing Byproducts

Arsenic and products containing arsenic are under an increasing barrage of criticism, because of their toxicity. This has produced a significant drop in demand. Increasing quantities of arsenic containing byproducts are accumulating as the production of heavy metals from complex and so-called dirtier concentrates increase. These products accumulate in the material circuits of the individual plant. Ultimately, arsenic-containing materials have to be removed from these circuits. The processes involved are expensive, and since the demand for arsenic is mostly inadequate, special measures must be taken to stabilize and concentrate these materials for disposal or storage.

Table 6 shows the distribution of arsenic in the different product phases of industrial smelting processes for the recovery of copper, zinc, and lead. Whereas in the copper smelting processes the main arsenic carriers are flue dusts and slags, in lead processing most of the arsenic reports to flue dusts and copper dross. In the hydrometallurgical processes for the recovery of zinc, the arsenic generally remains in the final iron residue (jarosite or goethite), which today still is mostly dumped in ponds.

It is common practice to return arsenic-containing phases to the smelting process several times to increase the arsenic concentration and to minimize the arsenic containing byproducts, which have to be further processed. The actual arsenic elimination from a smelter circuit depends on the fraction being recirculated.

In times of a stable or growing market for As_2O_3 and for arsenic metal the arsenic-containing byproducts from nonferrous metal smelters were a welcome source of these products. Today nonferrous metal smelters are under

increasing pressure from environmental legislation and quality requirements to separate the arsenic from their production circuits and to convert it to saleable products or treat it for safe disposal with no economic advantage.

Arsenic in Copper Smelters. The recovery of copper from sufidic concentrates includes the following process steps: copper matte smelting, converting of the copper matte, fire refining, anode casting, and electrolytic refining. During the pyrometallurgical operations, arsenic is mostly distributed between matte and slag or blister copper and slag (Table 3) while smaller quantities remain in the copper and have to be removed from the circuit during electrolytic refining. Whereas flue dusts from the matte smelting operation are often recycled to the furnace for arsenic enrichment, flue dusts from the converting operation are mostly treated for arsenic removal [54].

Figure 8. Flow sheet of the converter dust treatment operation at Saganoseki Smelter [56]

At Saganoseki Smelter, Japan the flue dusts from the converting section (5 – 8 % As, 20 – 25 % Pb, 1 – 4 % Cd, 1 – 2 % Fe, 2 – 4 % Bi, 10 – 16 % Zn, 4 – 6 % Cu) are hydrometallurgically converted to a $PbSO_4$ product which also contains Bi and Sb and is sent to a lead smelter, a Zn- and Cd-containing hydroxide product which is sent to a zinc smelter, and arsenic sulfide which is sufficiently stable for disposal.

Figure 9. Process for recovering metal values from materials containing arsenic [55]

Figure 8 shows a flow sheet of the process at Saganoseki Smelter; the corresponding analyses of the phases are listed in Table 7. The distributions of the elements in the product phases are given in Table 8. Initially the converter dust is leached with 40 g/L H_2SO_4. Zn, Cu, and As are transferred into solution, while Pb, Bi, and Sb remain almost completely in the $PbSO_4$ residue. For the removal of As from the solution, the pH is raised to 4 and As is oxidized from the trivalent to the pentavalent state. The As/Fe molar ratio is adjusted to 1/1.2 in the solution to support the dearsenification. The remaining elements in the solution are precipitated as hydroxides by neu-

tralization (pH 9 – 10) with sodium hydroxide. The As residue is leached again with H_2SO_4 and precipitated as arsenic sulfide by sulfidizing with sodium hydrogensulfide.

Figure 9 shows a multistage process in which Cu, Cd, and Zn are separated off in solution after a neutralization step. Arsenic is precipitated together with lead and the precious metals. Lead and the precious metals are dissolved in a further chloride – sulfate leaching step. During a subsequent alkaline leaching step, the As is dissolved as Na_3AsO_4 and then crystallized out. By adding iron(III) sulfates, the soluble arsenic constituents are precipitated. An iron arsenide residue suitable for disposal is obtained. Tests to determine the solubility of arsenic from such a residue in acidic solution revealed a content of < 0.4 ppm As after 5 d [55].

During the electrorefing of the copper anodes, As accumulates in the electrolyte. To reduce the impurity contents in the electrolyte, a bleed stream is diverted from the circuit and treated to recover Cu, Co, and Ni, usually by electrowinning. This leaves behind a sludge that typically contains 50 % Cu, 20 % As, 5 % Sb, and small amounts of Co, Ni and Bi.

At Sumitomo Metal Mining Corporation in Japan, this sludge is treated together with arsenic sulfide residue from the gas cleaning operation in the converter section. From these raw materials either marketable refined As_2O_3 or arsenic metal is produced, or copper arsenate is precipitated from a leach solution as an alternative product. The sludge from the electrolyte cleaning operation is leached with H_2SO_4, and selective leaching of the arsenic from the arsenic sulfide from the converter gas cleaning facilities is performed with caustic soda. Before neutralization, the two liquids are mixed to adjust the Cu/As ratio to 1.3 to 1.45. Copper and arsenic are precipitated as copper arsenate by neutralization with caustic soda [57].

Especially in Japan, where copper concentrate is mostly imported, the ability to process concentrates with high impurity contents might be an important factor in keeping raw material costs low and maintaining a stable position in the market.

Dearsenification of Lead – Copper Matte. A lead – copper matte containing 25.7 % Cu, 18.2 % Ni, 1.65 % Co, 27.2 % Pb, and 4.14 % As is leached with concentrated H_2SO_4 at 85 – 100 °C in the presence of MnO_2:

$$MS + MnO_2 + 2\,H_2SO_4 \longrightarrow MSO_4 + MnSO_4 + S + 2\,H_2O$$

(M = Cu, Ni, Co, and Pb)

The metals Ni, Co, Fe, and As dissolve, leaving a residue of elemental sulfur and $PbSO_4$. The residue is separated. As is precipitated as $FeAsO_4$ by addition of NaOH or $Ca(OH)_2$ at pH 4. The $FeAsO_4$ takes up 88 – 92 % of the arsenic. It consists of 24 % As, 22 % Fe, and 3 – 5 % Cu and is in a suitable form for safe disposal [58], [59]. As shown in Figure 10, the remaining solution is processed further to remove Co and Cu and recover MnO_2.

Figure 10. Flow diagram for recovery of cobalt, nickel, and copper from mattes [60]

Lead Smelter Flue Dusts. Arsenic-containing lead flue dusts can be leached with a 20 % H_2SO_4 at 90 °C. More than 90 % of the As, Zn, and Cd pass into solution. The residue rich in lead is returned to the lead production process. After removal of the indium from the solution by solvent extraction, the arsenic is precipitated with $Fe_2(SO_4)_3$ and $CaCO_3$ as an iron-containing arsenic residue suitable for storage in containers or for further treatment. Table 9 shows the typical composition of three different lead smelter flue dusts. Figure 11 shows a flowsheet [61]. Arsenic also can be precipitated with calcined zinc concentrates [59], H_2, Na_2S, or even NaHS. Either As_2S_3 or As_2S_5 is obtained [62].

Separation of Arsenic and Antimony from Flue Dusts. Since many flue dusts occurring in the nonferrous metals industries contain both arsenic and antimony, the question of the separation of these two metals arises if values of the two metals are comparable. Whereas arsenic now only has a small market and disposal is often preferred to a recovery from fumes, antimony still is of a noticeable economic value. Research is in progress to develop techniques for the separation of both metals. One possibility is the injection of oxygen into mixed arsenic/antimony oxide vapors to recover antimony oxide [63].

Figure 11. Flow sheet for treatment of lead smelter copper dross flue dust

Roasting of Tin Concentrates. In the roasting of tin ore concentrates in multiple-hearth furnaces, the atmosphere is regulated so that As volatises as As_4. One proposal for avoiding the production of nondisposable products is to adjust the oxygen and sulfur partial pressures so that the As_4 is converted by two additional burners, for example in a tube reactor, at 600 – 900 °C into disposable As_4S_4, which is recovered in the sump of a washer. The product is suitable for disposal or, if desired, may be worked up to give marketable products [64]

2. Arsenic Compounds

The most important use of arsenic compounds is the production of arsenic-containing wood

Table 9. Assays of lead smelter flue dust samples

Sample	Description	Assay, wt %								
		As	Pb	Zn	Cd	Sb	In	Cu	Fe	SO_4^{2-}
1	Composite sample	10.0	41.0	10.3	0.79	3.5	0.26	0.10	0.28	7.0

preservatives (see Chap. 3), although even here consumption is very much on the decline because of environmental pollution and toxicity [65–68].

2.1. Arsenic Trioxide

As_2O_3 [*1327-53-3*], M_r 197.8, is also known as white arsenic. It occurs in two crystalline and one amorphous modification. The octahedral (or cubic) modification, arsenolite, ϱ 3.86 g/cm^3, is stable at room temperature. It is formed on condensation of As_4O_6 vapor; As_4O_6 molecules are the lattice units. At temperatures above 221 °C, it changes into a monoclinic modification, claudetite, ϱ 4.15 g/cm^3. This modification is directly formed when condensation is carried out at temperatures above 221 °C. Condensation above 250 °C results generally in the formation of the amorphous, glassy phase, ϱ 3.70 g/cm^3, which devitrifies into the octahedral modification at room temperature.

In an open vessel, arsenic trioxide sublimes without melting above 135 °C. The monoclinic form melts at 312.3 °C under its own vapor pressure. Up to about 800 °C the vapor density corresponds to the formula As_4O_6; at 1800 °C, dissociation into As_2O_3 molecules is complete. The As_4O_6 molecules were also detected in nitrobenzene solutions.

Arsenic trioxide is moderately soluble in water. The glassy – amorphous As_2O_3 dissolves much more easily than the crystalline form; its solubility is 12 g/L at 2 °C and 114.6 g/L at 100 °C [69]. The solution has a sweetish taste with an unpleasant metallic tang. As little as 0.1 g can be fatal, if As_2O_3 enters the stomach.

For production of the oxide, see Section 1.5.1.

2.2. Arsenous Acid

Arsenous acid [*13464-58-9*] cannot be obtained from aqueous solutions of As_2O_3; instead, As_2O_3 is reprecipitated. However, in aqueous solution it exists in equilibrium with its dissociation products. It is still not clear what formula should be assigned to dissolved arsenous acid. In addition to the formulation as orthoacid, H_3AsO_3 or $As(OH)_3$, which is used here, the dissolved acid may also be formulated as metaacid, $HAsO_2$ or AsO(OH), or as hexahydroxoacid, $H_3[As(OH)_6]$. Arsenous acid is amphoteric, dissociating in two ways:

$$As(OH)_3 \rightleftharpoons AsO(OH)_2^- + H^+$$

$$As(OH)_3 \rightleftharpoons As(OH)_2^+ + OH^-$$

The dissociation constants are 6×10^{-10} and 1×10^{-14}, respectively. Accordingly, arsenous acid is a very weak acid, approximately equal in strength to boric acid, but it is a much weaker base. The As^{3+} ions occur in significant quantities only in very strongly acidic solutions.

Arsenates (III). The salts of arsenous acid are called arsenates(III). Formerly they were called arsenites. Some salts exist in the forms MH_2AsO_3, M_2HAsO_3, and M_3AsO_3, although most salts of arsenous acid are derived from the metaacid, $HAsO_2$, i.e., have the formula $MAsO_2$.

The alkali metal arsenates(III) dissolve easily in water, whereas the alkaline earth metal arsenates(III) are slightly soluble to insoluble. The compounds of arsenous acid with heavy metals are insoluble in water. Arsenous acid can be retained in considerable quantities by slimy metal oxide hydrates, such as iron oxide hydrate by adsorption.

The arsenates(III) are decomposed by strong acids because they are salts of a very weak acid.

Sodium arsenate(III), $NaAsO_2$ [*7631-89-2*], does not exist in crystallized form. Solutions of the salt are obtained by dissolving arsenic trioxide in sodium hydroxide. For manufacture, arsenic trioxide is mixed with caustic soda. After the addition of a little water, a vigorous reaction begins, spreading quickly through the mixture. Soda may also be mixed with the oxide and a little water, and the resulting mixture dried at elevated temperature in a furnace. In both cases, a water-soluble product is obtained after grinding. It is used in the manufacture of insecticides, herbicides, etc.

Other arsenates(III): Many complex metal arsenates(III) are known. They include *Scheele's green*, formerly used as an artist's color. It is a mixture of copper arsenates(III) to which formulas such as $Cu_3(AsO_3)_2$, $CuHAsO_3$, and $Cu(AsO_2)_2$ have been assigned. The double salt of copper arsenate(III) and copper acetate, $Cu(CH_3COO)_2 \cdot 3\,Cu(AsO_2)_2$, is *Schweinfurth green*, another artist's color. This use has declined enormously because of the poisonousness. Calcium and copper arsenates(III) were formerly used as "*copper-arsenic liquor*," to control pests in viticulture.

2.3. Arsenic Pentoxide

Arsenic pentoxide, As_2O_5 [*1303-28-2*], M_r 229.8, is a white glassy mass (ϱ 4.32 g/cm^3), which deliquesces in air to form arsenic acid. On heating, arsenic pentoxide begins to decompose near its melting point, ca. 300 °C. The vapor consists of arsenic trioxide and oxygen. The pentoxide can be prepared by reaction of arsenic trioxide with oxygen under pressure or by dehydration of crystalline arsenic acid at temperatures above 200 °C [70]. The crystal structure was unknown until recently. The monocrystals were grown under oxygen excess pressure: space group $P2_12_12_1$ [71], [72].

2.4. Arsenic Acid

Arsenic acid, H_3AsO_4 [*7778-39-4*], is known in the solid state only as the hemihydrate $H_3AsO_4 \cdot 0.5\,H_2O$ in the form of rhombic, deliquescent crystals. Solutions in water behave as a tribasic acid with the dissociation constants $K_1 = 5.6 \times 10^{-3}$, $K_2 = 1.7 \times 10^{-7}$, and $K_3 = 3 \times 10^{-12}$. Arsenic acid loses water when heated to 120 °C with the formation of pyroarsenic acid, $H_4As_2O_7$. At higher temperatures, more water is lost and metaarsenic acid, $HAsO_3$, forms [70]. If the protons of the acids are completely or partly replaced by metals, the arsenates(V), which generally correspond to the phosphates, are formed. In acidic solution, arsenic acid and its salts are strong oxidizing agents.

Production. Arsenic acid is produced solely by the oxidation of As_2O_3. Various processes for its production based mostly on oxidation with nitric acid, which gives a high yield, are described in the patent literature. Originally the apparatus used for those processes were usually made of stoneware but they are now made of alloys resistant to nitric acid.

The plant usually consists of so-called developers and a regenerator for nitric acid. The developers are ca. 4-m^3 vessels equipped with a high-speed stirrer, a steam coil, and a mechanical feeder for oxide. About 2000 L of 38 % HNO_3 is introduced initially, and the oxide is run in with strong heating until the nitric acid has been consumed. The oxides of nitrogen formed pass from the developer into the regenerator, where they are worked up to nitric acid in the presence of air and water. Up to 90 % of the NO and NO_2 formed are converted back into nitric acid. One developer can process 2000 kg of As_2O_3 into arsenic acid in 24 h.

Oxidation with sodium or calcium chlorate also enables a relatively large quantity of oxide to be oxidized in a short time. The oxide is suspended in water and a little arsenic acid is added to the resulting suspension. An aqueous solution of the chlorate is run in at boiling temperature. The reaction takes place smoothly while chlorate is uniformly run in. The input of chlorine must be reduced towards the end of the reaction because otherwise chlorine readily escapes. The arsenic acid obtained by the chlorate process always contains chloride, which causes problems in the production of lead arsenate.

Arsenic acid is used as a defoliant and as a starting material for important inorganic and organic arsenic compounds.

Arsenates(V). Arsenic acid gives three series of salts. They correspond generally to the phosphates in their compositions and solubilities. Many of them are also isomorphous with the phosphates, e.g., ammonium magnesium arsenate(V), $MgNH_4AsO_4 \cdot 6\,H_2O$, which changes on calcination into magnesium pyroarsenate(V), $Mg_2As_2O_7$, a form suitable for the quantitative determination of arsenic acid. Unlike silver phosphate, which is yellow, the silver salt Ag_3AsO_4 is brown.

Of the numerous salts of arsenic acid, the salts of potassium, sodium, calcium, and lead are important commercially. Even today they are used on a wide scale in pest control, although modern synthetic organic compositions have reduced the use of arsenates. In some countries, the use of arsenic compounds in plant protection agents has been banned. The same applies to metal arsenates(V) as active constituents of arsenic-containing wood preservatives [73], [74].

*Monopotassium arsenate(*V*),* KH_2AsO_4, M_r 180.04, *mp* 288 °C, ϱ 2.867 g/cm^3, was used in the manufacture of insecticides and in the preservation of skins. It is prepared by calcining a mixture of equal parts of arsenic oxide and potassium nitrate in cast-iron cylinders, leaching the melt with water, and concentrating the solution with arsenic acid. It forms white crystal crusts.

*Trisodium arsenate(*V*),* M_r 423.9, ϱ 1.759 g/cm^3, *mp* 86.3 °C, is obtained most easily by neutralizing arsenic acid with sodium carbonate or sodium hydroxide. Concentration by evaporation gives a marketable product having the formula $Na_3AsO_4 \cdot 12\,H_2O$.

Disodium arsenate(V), Na_2HAsO_4, M_r 185.9, ϱ 1.72 g/cm^3, is obtained by roasting a mixture of arsenic oxide with sodium carbonate and sodium nitrate in the presence of air. In addition, this compound can be easily obtained by calcining sodium arsenate(III) in the presence of air. Sodium arsenate(V) is used in the production of other arsenates, such as calcium and lead arsenates.

*Calcium arsenates(*V*).* There are three known calcium salts of arsenic acid, $Ca(H_2AsO_4)_2 \cdot H_2O$, $CaHAsO_4 \cdot H_2O$, and $Ca_3(AsO_4)_2 \cdot 3\,H_2O$. In addition, there are basic salts, for example, $Ca_5OH(AsO_4)_3$, which corresponds to apatite. Commercial preparations are based on the neutral salt. However, different manufacturers use different methods and do not always guarantee the production of a strictly neutral salt. Because of the risk of damage to plants that acid arsenic salts involve, a basic character is given to the commercial product during its production by using excess lime. Elevated temperature, abundant moisture, and atmospheric carbon dioxide cause calcium arsenate to convert into the plant-damaging acid arsenate:

$$Ca_3(AsO_4)_2 + CO_2 + H_2O \longrightarrow 2\,CaHAsO_4 + CaCO_3$$

The reason the acid salt is harmful is its greater solubility in water, 0.31 % As_2O_5 vs. 0.013 % for the neutral salt. The neutral salt begins to turn acid only after the excess lime added has been converted completely into carbonate. For the solubility in the presence of atmospheric carbon dioxide, see [68].

Calcium arsenate(V) is generally prepared by reacting milk of lime with arsenic acid. Maintaining a certain temperature and an experimentally determined feed rate and stirring speed, the arsenic acid can be run as a fine distribution into the milk of lime. The precipitate obtained is filtered, washed, and dried.

Calcium arsenate(V) is also obtained by heating calcium arsenate(III) in a stream of dry air.

Lead arsenate(V), $PbHAsO_4$, M_r 347.12, is a white water-insoluble powder of density ϱ 5.79 g/cm^3. It was marketed as a plant protection agent in the form of powders and pastes. It is produced mainly from lead acetate, lead nitrate, and lead oxide and disodium arsenate. The direct reaction of arsenic acid with litharge in the presence of nitric acid gives a dilead arsenate. Commercial lead arsenates contain mostly $PbHAsO_4$ along with varying amounts of $Pb_3(AsO_4)_2$. Accordingly, their lead content is higher and their As_2O_3 content lower than the levels calculated for $PbHAsO_4$.

Arsenic-containing plant protection agents have been banned in Europe. However, they are still used in East Asia [73], [74].

2.5. Arsenic Sulfides

Table 10 shows some physical data of the arsenic sulfides [69], [75].

Table 10. Physical data of arsenic sulfides

		Color	M_r °C	*mp,* °C	*bp,*
Arsenic disulfide (realgar)	As_4S_4	red	427.9	307	565
Arsenic(III) sulfide (orpiment)	As_4S_6	yellow	492.1	320	707
Arsenic(V) sulfide	As_4S_{10}	yellow	620.3	>95 decomp.	–

Arsenic disulfide, As_4S_4 (realgar, red arsenic glass, red glass, ruby arsenic, arsenic blend), occurs in ruby-red crystals or as an amorphous reddish mass. Its commercial value is determined less by the chemical composition than by its purity and fineness. Industrially produced red arsenic glass varies in its composition. Whereas the red glasses previously contained 70 % As and 30 % S, substantially corresponding to the formula AsS, they now contain around 61 – 64 % As and 39 – 36 % As. The red glass is marketed in finely divided form.

Red glass has long been produced on a large scale from arsenic ores and sulfur ores or from arsenopyrite containing iron pyrites. Another industrial process based on production from arsenous acid and sulfur has been perfected. Prolonged development problems were presented by discolored products that had to be converted into an attractive, marketable red glass. The red glass is produced in two separate steps. A red glass that does not yet have the desired composition and that needs refining in appearance is obtained in the first step by melting and sublimation. The intermediate product is therefore refined and is given the required color.

Production by melting a mixture of elemental arsenic and sulfur gives a red glass particularly fine in appearance but too expensive on account of the high price of the elemental arsenic. The processing of arsenopyrite and sulfur, although possible, is not usual.

Most red glass is used in tanneries as a depilatory in the manufacture of fine leather.

Arsenic(III) sulfide, As_4S_6, occurs as a yellow mineral known as orpiment. It can be produced by precipitation of compounds of trivalent arsenic with hydrogen sulfide. The colloidal solution of the arsenic trisulfide can be flocculated by hydrochloric acid, in which it is insoluble. However, it dissolves readily in basic reagents, above all in alkali-metal sulfide solutions, including ammonium sulfide, to form thioarsenites:

$$As_2S_3 + 3\,S^{2-} \longrightarrow 2\,[AsS_3]^{3-}$$

If yellow ammonium hydrogen sulfide is allowed to act on arsenic trisulfide, the dissolved sulfur promotes oxidation to thioarsenate:

$$As_2S_3 + 3\,S^{2-} + 2\,S \longrightarrow 2\,[AsS_4]^{3-}$$

Arsenic trisulfide is a lemon-yellow compound, which begins to sublime before melting, melts at 310 °C to form a red liquid, and boils at 707 °C without decomposing. It is used as an artist's color, marketed in pure form as king's yellow. The impure product obtained by fusing arsenic trioxide with sulfur is marketed as orpiment. Orpiment always contains unchanged arsenic trioxide and, unlike the pure sulfide, is poisonous.

Orpiment was once used for cosmetic purposes. It is now used in the semiconductor industry, for the production of IR-permeable windows, and as a pigment.

Arsenic(V) sulfide, As_4S_{10}, is produced by fusing stoichiometric quantities of As and S powder or by precipitation from highly acidic arsenate(V) solution with H_2S. At relatively high temperatures As_4S_{10} decomposes into arsenic(III) sulfide and sulfur.

2.6. Arsenic Halides

The known arsenic halides are listed in Table 11 [69], [75], [76].

All arsenic halides can be produced by direct combination of the components. They can also be obtained by halogenation of the oxides or sulfides. The bonds are hydrolyzed by water. Only arsenic(III) chloride is commercially significant.

Table 11. Physical data of arsenic halides

	Form	M_r	*mp*, °C	*bp*, °C
Arsenic(V) fluoride	colorless gas	169.9	−88.7	−58.2
Arsenic(V) chloride		252.2	−50 (decomp.)	–
Arsenic(V) oxychloride	colorless liquid	197.3	−78	–
Arsenic(III) fluoride	colorless liquid	131.9	− 8.5	60.4
Arsenic(III) chloride	colorless liquid	181.3	−13	130.2
Arsenic(III) bromide	yellow solid	314.6	31	221
Arsenic(III) iodide	red solid	455.6	140.7	ca. 400

Arsenic trichloride, $AsCl_3$, is a colorless oily liquid that fumes in air, ϱ 2.17 g/cm^3. By virtue of its low boiling point, $AsCl_3$ is easy to separate from $SbCl_3$ and the chlorides of other metals. $As(OH)_3$ forms during hydrolysis. The direct synthesis of $AsCl_3$ is uneconomical. An old commercial production method is the Glauber process using arsenic trioxide:

$$As_2O_3 + 6\,NaCl + 3\,H_2SO_4 \longrightarrow 2\,AsCl_3 + 3\,Na_2SO_4 + 3\,H_2O$$

However, $AsCl_3$ is easier to produce by reacting As_2O_3 with gaseous hydrogen chloride at 180 – 200 °C.

Arsenic(III) chloride is a starting material for numerous organoarsenic compounds and for the preparation of chlorine derivatives of the arsines. It is used as a dopant in the manufacture of semiconductors and in the production of high-purity arsenic metal (see page 16) [77].

2.7. Arsenic Hydride and Arsenides

Arsenic hydride, AsH_3, arsine, M_r 77.95, *bp* −55 °C, *mp* −116.3 °C, is the only known hydrogen compound of arsenic; it is a colorless gas with an unpleasant, garlic-like odor. It is extremely toxic: in many cases the inhalation of small amounts has caused death. Arsine does not ignite spontaneously but burns with a grayish-blue flame to form arsenic trioxide. If the flame is extinguished, for example, by holding a cold porcelain dish in it, arsenic is deposited as a black patch. The pure gas is stable at normal temperature. If arsenic hydride is passed through a red-hot glass tube, it decomposes into hydrogen and arsenic (arsenic mirror), 185.1 kJ being released per mole of arsenic. The arsenic is deposited just behind the heated area as a bright, metallic black mirror (Marsh test). When treated with hypochlorite solution or with alkaline hydrogen peroxide solution, the patch changes into soluble arsenate. Arsenic hydride has a strong reducing action. It precipitates metallic silver from silver nitrate solution. It reacts with solid silver nitrate to form the yellow compound $AsAg_3 \cdot 3\,AgNO_3$ (Gutzeit arsenic test).

Arsine cannot be prepared by direct synthesis. The most convenient method of production is the reaction between sodium arsenide and water or zinc arsenide and dilute hydrochloric acid:

$$As_2Zn_3 + 6\,HCl \longrightarrow 2\,AsH_3 + 3\,ZnCl_2$$

These reactions are fast and complete and have the advantage that the product is not contaminated with hydrogen. Arsenic hydride can also be produced by cathodic reduction or by reduction of arsenic compounds in acidic solution with zinc or magnesium. The last reaction is not quantitative because elemental arsenic, which does not react, precipitates. The product also has a high hydrogen content. Because arsenic is present as a common impurity in numerous metals suitable for the production of hydrogen, hydrogen produced by acid – metal reduction must be passed through a potassium permanganate solution to destroy any arsenic hydride present. Particular practical significance is attributed to the formation of arsenic hydride in the pickling of metals when arsenic-containing sulfuric acid is used.

Arsenic hydride is so poisonous that a few inhalations of air containing arsenic hydride can result in death. The MAK is 0.2 mg/m^3.

Arsenic hydride is used as a dopant in the semiconductor industry [77].

Arsenides. A number of arsenides occur in nature. Some have a defined composition, others are probably mixtures. Naturally occurring arsenides include Cu_3As (domeykite), $FeAs_2$

(löllingite), $NiAs_2$ (chloanthite), NiAs (niccolite), and $CoAs_2$ (smaltite). There are many minerals in which sulfur is partially replaced by arsenic.

The arsenides themselves have little commercial significance. Those produced are obtained by direct synthesis. The alkali metal arsenides are also obtained by reaction in liquid ammonia. However, in this case polyarsenides can form in addition to the simple arsenides. The arsenides of the alkali metals, alkaline earth metals, zinc, etc., are rapidly decomposed by water and acids with the formation of arsine. They may be regarded as derivatives of arsenic hydride. Most of the heavy metal arsenides, whose composition often does not reflect any simple relationship to arsenic hydride, are intermetallic phases and are highly resistant to acids. Gallium and indium arsenides are important in the semiconductor industry (see Section 3).

2.8. Organoarsenic Compounds

There are several known organoarsenic compounds. Intensive research began with the discovery by P. Ehrlich in 1908 of chemotherapeutic efficacy of organoarsenic compounds against trypanosomes and spirochetes (which cause sleeping sickness and syphilis). Aromatic organoarsenic compounds were successfully used for some time in the treatment of tropical diseases; compounds containing aliphatic organic groups were effective plant protection agents and pesticides. Since then the use of organoarsenic compounds has greatly diminished because of the introduction of antibiotics, such as penicillin, and the increased awareness of the environment [78]. Basic research, with a view to understanding the behavior of arsenic in the environment, has greatly increased over the last decade.

Monographs on organoarsenic compounds can be found in [4], [79–84]. Annual reviews are published in the Journal of Organometallic Chemistry [85], [86]. The recurring theme of these publications is the synthesis of new ring systems and their structural elucidation [87–94] and the refinement of analytical techniques [95–102]. A large number of publications are concerned with the metabolism and toxicity of organoarsenic compounds in organisms [103–112]. For chemotherapeutic uses, see [113], [114]. Today arsenic compounds are no longer used in the treatment of syphilis and are only rarely used in the treatment of amoebiasis, although they are still prescribed for the treatment of trypanosomal diseases (e.g., sleeping sickness), above all during advanced stages of the sickness [114]. Because the agricultural use of organoarsenic compounds as plant protection agents and pesticides always results in residues, the organoarsenic compounds have largely been replaced by metal-free compounds. In Europe agricultural use of arsenic compounds has been banned; in the USA, certain preparations are still accepted in some states, e.g., those of the Ansar series. In Eastern Asia preparations such as Neoasozin are essential rice fungicides. In wood preservatives, arsenic compounds are used only in compound preparations. In the Federal Republic of Germany, France, and Switzerland, their use is restricted or prohibited [73].

Nomenclature. Nomenclature is governed by the provisional IUPAC Rule D-5 [115], which suggests the following names (R = organic residue):

Arsines: the organic derivatives of arsenic hydride with the general formulas $RAsH_2$, R_2AsH, and R_3As (primary, secondary, and tertiary arsines).

Arsonium salts: $(R_4As)^+$, analogous to the ammonium salts.

Arsonous acid: 
Arsinous acid: 
Oxoorganoarsines: compounds of the type $(R{-}As{=}O)_n$. The name "arsenoso" used by analogy to the nitroso compounds is misleading because, corresponding to the oligomeric form of these compounds, there are no analogies to the nitroso compounds [79].

Arseno compounds: the type R−As=As−R would correspond to the azo compounds; however, valence saturation is achieved by polymerization $(R{-}As)_n$ in the case of arsenic. This name has been retained by several authors in the interests of simplicity [79], [88].

Arsonic acid: 
Arsinic acid: 
Arsorane: R_5As

Arsa: to be used as a prefix when arsenic is bound as part of a ring. Many compounds of this type are also called by trivial names taken from the *N*-heterocycles [79], [80].

The covalent/ionic bond problem is discussed in [79]. In the Anglo-Saxon literature, some of the nomenclature also follows the Chemical Abstracts rules [116].

2.8.1. Aliphatic Organoarsenic Compounds

Compounds of this class are still used as herbicides and fungicides in rice, cotton, fruit, and coffee plantations, particularly in Eastern Asia:

1) Salts of methanearsonic acid, $CH_3AsO(OH)_2$, especially the iron ammonium salt, Neoasozin, used as a fungicide in rice growing and the sodium, ammonium, and diethanolammonium salts used as herbicides in cotton growing.
2) Dimethylarsinic acid, $(CH_3)_2AsOOH$ cacodylic acid. Ansar 160, the sodium salt, is used as a total herbicide and desiccant. Generally it is produced by reaction of methyl halide with a salt of arsenous acid.
3) Methylarsine sulfide, $CH_3-As{=}S$, Urbasulf, was prepared by reduction of the sodium methylarsonate with SO_2, followed by reaction with H_2S. It is no longer on the market. Urbacid, methylarsine bis(dimethyldithiocarbamate), $CH_3-As[S-CS-N(CH_3)_2]_2$, formerly used in rice and coffee growing, is no longer available commercially. It was prepared from methyldichloroarsine and dimethyldithiocarbamate.

2.8.2. Aromatic Organoarsenic Compounds

These compounds were used for some time as chemotherapeutic agents for treating protozoal infections (→ Chemotherapeutics). Their importance has declined since the introduction of antibiotics. Preparation is based on two classic methods. Aniline is reacted with arsenic acid at 200 °C as in the sulfonation of organic compounds [117]:

$$C_6H_5NH_2 + H_3AsO_4 \longrightarrow H_2N-C_6H_4-AsO(OH)_2$$

Or, diazo compounds are reacted with sodium arsenate(III) [118–120]:

$$C_6H_5N_2Cl + Na_3AsO_3 \longrightarrow C_6H_5-AsO(ONa)_2 + N_2 + NaCl$$

This reaction was the more important commercially. Various modifications [121], e.g.,

$$C_6H_5NH_2 + HNO_2 + AsCl_3 + H_2O \longrightarrow C_6H_5-AsO_3H_2 + N_2 + 3\,HCl$$

have proved successful in special cases where the usual processes fail.

In one modern process [122], arsenic acid complexed with EDTA is added at 130 °C to a solution of excess aniline in perchloroethylene. The water of reaction and unreacted aniline are separated off, and the bis(4-aminophenyl)arsinic acid intermediate is converted by acidic hydrolysis into arsanilic acid, $NH_2C_6H_4-AsO(OH)_2$. Some arsonic acids are still used in raising livestock. 3-Nitro-4-hydroxyphenylarsonic acid is used as a feed additive against coccinid infections in poultry farming. In Germany, however, animal feed additives are controlled by legislation [123].

The main use of the arsonic acids was in their further processing to arsenobenzenes and "arsenic oxides" by reduction with SO_2, phosphorus trichloride, sodium dithionite, phosphorous acid, or $SnCl_2$. Reduction with zinc dust and hydrochloric acid gives the arsines, which are reoxidized simply on standing in air. For example, phenylarsine, $C_6H_5-AsH_2$, rapidly changes in air into the arseno compound $(C_6H_5-As)_n$. Further uptake of oxygen is considerably slower unless catalyzed, e.g., by iron.

The arsenic oxides $R-As{=}O$ are fairly stable. All compounds are oxidized to arsonic acid derivatives by relatively strong oxidants, including hydrogen peroxide, halogens, and Chloramine-T (sodium *p*-toluenechlorosulfonamide).

The aromatic arsonic acids are dibasic. Aqueous solutions of the monosodium salts are neutral to mildly acidic; those of the disodium salts

are moderately alkaline (pH 8 – 9). Calcium and magnesium salts are usually soluble in cold water, but when heated they precipitate as virtually insoluble deposits. This solubility in cold water may be used to separate arsonic acids from arsenic acid, whose calcium and magnesium salts precipitate from cold solutions. Heavy metal salts are insoluble. The arsonic acids generally crystallize well. The stability of an arsonic acid depends on the substituents on the benzene ring. A nitro group in the meta position destabilizes the bond to the arsono residue; thus, diazotized *m*-nitro-*p*-aminophenylarsonic acid loses arsenic on heating. The arsono residue can weaken the bond to the nitro group in the *meta* position, bringing about exchange with a hydroxyl group. Only a few arsonic acids have been used in therapy. Some arsonic acids form azo dyes that contain both arsonic acid and sulfonic acid groups. They are used in the analysis of metals. One example is arsenazo-III, 2,7-bis(*o*-arsonophenylazo)chromotropic acid [124].

Aromatic Arsenobenzenes. For some time arsenobenzenes were the only organic arsenic chemicals used in therapy. They are oxidized in the organism to arsenic oxides, the actual therapeutic agents. Probably the most important compound was 3,3′-diamino-4,4′-dihydroxyarsenobenzene, or Salvarsan, used to treat syphilis.

Properties. The aromatic arseno compounds are yellow substances. Compounds containing amino or hydroxyl groups are soluble in acids and alkalis. The introduction of formaldehyde sulfoxylate or formaldehyde hydrogen sulfite into the amino group makes the aromatic arseno compounds soluble in water. In aqueous solution the salts are hydrophilic colloids. The toxicities and effects of the arseno compounds depend on the degree of association and size of the molecule of the dissolved arsenobenzene. Minor changes in the production process can significantly affect the quality as a chemotherapeutic agent. The arsenobenzenes cannot be purified by crystallization or identified by a melting point. The original assumption that arsenobenzenes contained an arsenic – arsenic double bond had to be revised when cyclic and chain polymers were shown to be present [125].

Organic Oxoarsenic Compounds ("Arsenic Oxides"). The reduction of organoarsenic compounds can be controlled by using a suitable reducing agent so that reaction stops at the desired intermediate stage. This is not the case for oxidation. In the most widely used method for the production of organic oxoarsenic compounds from arsonic acids, the acid is directly reduced to the anhydride of the arsonous acid with SO_2. Hydrolysis of aryldihaloarsines is also a possibility.

Properties. The organic oxoarsenic compounds are the anhydrides of the arsonous acids. They are extremely poisonous, amphoteric substances sparingly soluble in water. They dissolve in acids and alkalis to form salts and can be precipitated from those solutions by carbon dioxide or ammonium chloride. The considerable significance attributed to sulfur-containing groups of the protein molecules in tissue and in ferments so far as biological functions are concerned and also the high affinity of arsenic oxides for cell thiols made it clear at a very early stage that the reaction between those two groups is responsible for the activity and toxicity of these compounds. The reaction takes place by formation of dithioarsenites:

$$R-As=O + 2\,R'SH \longrightarrow R-As\begin{matrix}\diagup SR' \\ \diagdown SR'\end{matrix} + H_2O$$

The resulting enzyme blockage can be reversed by a thiol.

3. Uses and Economic Aspects

The demand for metallic arsenic is limited. It is used in nonferrous alloys, and high-purity arsenic is used in electronic and semiconductor devices. The addition of ca. 0.5 % As to the lead grid in lead – acid storage batteries increases endurance and corrosion resistance. Additions of the same order to copper alloys improve high-temperature stability, recrystallization temperature, and corrosion resistance. The addition of up to 2 % As improves the sphericity of lead shot [1].

High-purity arsenic (at least 99.999 %) is used in electronics in conjunction with gallium or indium for the production of diodes (LED), infrared detectors, and lasers. Solar cells based on gallium arsenide have an efficiency of

20 % [126]. Among the semiconductors, silicon-based materials still dominate the market and will continue to do so in future because their production costs are far lower that those of the gallium arsenide semiconductors. Certain niches of properties which can not be provided by the silicon based semiconductors are filled by gallium arsenide, but although this marked is growing, it will be limited in the future [10], [127].

Most arsenic is used in the form of compounds, arsenic trioxide being the sole starting material. Arsenic compounds are used in the following fields:

1) Forestry: the use of arsenic trioxide as raw material for the production of wood preservatives today is its main application. The actual product is chromated copper arsenate (CCA), which is still hard to replace with other chemicals as far as effectiveness is concerned. A number of countries have forbidden the use of CCA as wood preservative The United States and Malaysia are the largest consumers. Because of the worldwide of environmental awareness and stricter regulations the almost monopoly consumer position of the United States makes the As_2O_3 market risky. In 1979 consumption of arsenic trioxide in agricultural chemicals in the United States was about 13500 t/a, but it dropped to 5000 t/a in 1991 [10], [16], [128], [129], [130]
2) Agriculture: herbicides and insecticides for cotton, coffee, and rice.
3) Industrial chemicals: electrolyte purification in the electrolytic recovery of zinc [131], metal pickling baths containing phosphoric acid.
4) Glass industry: fining agents and decolorizers [132].

The distribution of the arsenic use in the United States in the different fields of application are shown in Table 12. Overall consumption has remained constant at ca. 20 000 t/a for over ten years.

The wordwide production of arsenic trioxide is listed in Table 13. Total arsenic trioxide production underwent major changes since 1978. Production reached a peak in the mid-1980s and and has since been in decline, and at the same time the main producing countries changed completely. In 1978 Sweden, France, and Mexico were the largest producers; today's market is dominated by China, Chile, and the former Soviet Union. The main As_2O_3 producing companies are listed in the following:

China	not published
Chile	Cia Minera El Indio (CMEI)
Former Soviet Union	locations in the Urals, Altai, Kazahstan
Mexico	Industria Minera Mexico SA (IMM)
Philipines	not published
France	Societe Minere et Metallugique de Penarroya
Belgium	Metallurgie Hoboken-Overpelt (MHO)

In the 1980s Asarco in the United States stopped its As_2O_3 production, Boliden in Sweden shut down its production of arsenical products because of environmental problems, Salsigne in France declared bankruptcy, and China emerged as the world's largest producer of both arsenic trioxide and arsenic metal. Only China and Chile have countered the trend toward decreasing arsenic production [1], [10].

Arsenic metal accounts for only 3 % of the world demand for arsenic, mostly commercial grade (99 %). High-purity arsenic metal is produced by about ten companies. Furukawa Electric in Japan and Preussag in Germany are believed to be the largest producers, with reported capacities of 30 and 15 t/a, respectively [10].

Prices for arsenic trioxide are not readily available from published sources. As an average price for mexican As_2O_3 25 cents per pound can be found [10]. The price for arsenic metal was 55 – 60 cents per pound in October 1996 [135].

The largest consumers of arsenic trioxide are the United States, Malaysia, and the United Kingdom, in that order. Malaysia uses arsenic-based herbicides in its rubber plantations; the United Kingdom imports As_2O_3 and exports arsenic-containing pesticides and wood preservatives [133].

4. Stabilization of Arsenic for Safe Disposal

Because of the rapidly shrinking market for arsenic and its compounds, the focus of the research activities today lies more on the stabilization of arsenic-containing phases for safe disposal than on the production of arsenic-containing products. In some cases even As_2O_3-containing flue dusts that already have high arsenic contents are further processed for subse-

Table 12. Arsenic consumption in the United States in tons of As_2O_3 content per year [133], [10]

quent disposal. Besides disposal in a highly concentrated form like As_2O_3 or even arsenic metal in special dumping areas, the most promising development is the stabilization as arsenate. The occurence of arsenates in nature and as ageing products on older arsenic-containing dumping sites suggests stability under weathering conditions. As an alternative to arsenates, the precipitation of sulfides has been tested and applied, although arsenic sulfides seem to be less stable. Especially Fe, Ca, Ba, Mg, and Sr arsenates are regarded as extremely stable. Today the preferred species is iron arsenate, which is not only among the most stable arsenates under weathering conditions and under the influence of atmospheric CO_2, but also the cheapest as far as additional chemicals are concerned.

The process parameters which most affect the stability of the arsenate precipitate are the temperature, the pH during precipitation, and the speed and method of addition of the precipitants. The stability of iron arsenate is further increased by a molar ratio Fe/As > 4 and by the presence of small quantities of Zn, Cu, and Cd. For such iron arsenates solubilities of < 0.2 mg/L As were measured in long-time tests (about three years). When precipitated under atmospheric pressure below 100 °C, amorphous iron arsenate is formed. Precipitation at 120 °C under the corresponding pressure leads to the formation of skorodite crystals with a structure similar to the naturally occuring mineral. The solubility of the crystallic iron arsenate 100 times lower than that of the amorphous phase. The production of iron arsenate from arsenic-

containing intermediate products in the nonferrous metals industry for subsequent disposal is in industrial use at various locations.

Stabilization of arsenic in pyrometallurgical slags has been investigated as an alternative to hydrometallurgical stabilization. Silicate slags seem to be less soluble than basic slags, but the attainable arsenic concentration in silicate slags (ca. 1 %, possibly up to 5 %) is fairly low [20], [54], [136–156].

5. Recycling

Recycling of arsenic-containing products to recover the arsenic content is presently of no economical interest. The increasing demand for GaAs in the electronic industry will lead to the question of the recovery of the gallium content from electronic scrap in the future because Ga is comparatively rare and therefore expensive. However, the aim of the recycling process as far as arsenic is concerned is stabilization and subsequent disposal. The smelting of GaAs scrap with a liquid copper alloy to collect arsenic while oxidizing the gallium into a soda/silica slag is one attempt to solve this future recycling problem [157].

6. Safety Measures

Although pure metallic arsenic is not poisonous, the occurrence of toxic arsenic oxides formed by oxidation in air is unavoidable. In handling or manufacture of arsenical materials, inhalation of dust and skin contact with arsenic-containing gases must be prevented. In the absence of adequate safety measures the following jobs involve a risk:

- metal recovery/contamination by arsenic
- roasting of iron pyrites
- processing of arsenical minerals
- production of arsenic-containing pharmaceuticals
- use in pyrotechnics
- burnishing of metal surfaces
- use of arsenic-containing raw materials in the glass industry
- repair or cleaning of flue-dust plants, filters, etc.
- use in wood preservatives.

All work involving arsenic or its compounds should be carried out in sealed containers. In filling and emptying of apparatus, adequate measures must be taken to ensure that the maximum allowable concentrations (MAK values) are not exceeded. A dust-free working environment should be ensured by maintaining reduced pressure in the apparatus or by an adequate exhaust system.

Sampling must be carried out only with the aid of suitable equipment, e.g., air locks, vacuum injectors, and sealed sampling vessels. Rooms used for work involving arsenical materials should be adequately ventilated and dust free. If there is a general danger of inhaling arsenical materials, e.g., during open sampling, respirators must be worn. In relatively heavily dust-laden atmospheres, special protective clothing should be worn to prevent any skin contact with arsenic. The arsenic content in the air of the working environment should be monitored continuously [158].

The MAK for AsH_3 in air is 0.16 mg/m^3 [158]. In Germany, arsenic trioxide, arsenic pentoxide, arsenous acid, arsenic acid, and their salts are included in the list of carcinogenic working materials. All work involving arsenic and its compounds is governed by the regulations for dangerous materials (TRK) [158].

In every country there are special provisions for packaging, identification, storage, and transportation of arsenical products. The dangers involved in the use of arsenical preparations are not treated as seriously in the United States as in the EEC, where generally speaking such preparations are completely banned.

7. Toxicology

Nearly all arsenic compounds are considerably toxic, especially the inorganic ones.

The trivalent arsenic compounds, such as arsenic trioxide, As_2O_3, arsenic trifluoride, AsF_3, arsenic trichloride, $AsCl_3$, and arsine, AsH_3, are markedly more toxic than the pentavalent compounds. Elemental arsenic itself is not appreciably toxic, but it is converted readily to toxic compounds in the organism. Pure arsenic(III) sulfide, As_2S_3 [*12255-89-9*], also seems to

have a comparatively low toxicity, but often the crude sulfide is contaminated by arsenic trioxide. In contrast, some pentavalent organic compounds have been used as therapeutics; these benzenearsonic derivatives contain a stable carbon – arsenic bond and are practically not converted to inorganic arsenicals [159].

Arsenicals can cause acute, subacute, and chronic poisoning. However, acute poisoning is rare in comparison to subacute or chronic poisoning.

Absorption. Arsenicals can be absorbed mainly by ingestion and inhalation, and also through the skin. They are widely distributed within 24 h into different tissues, mainly the liver, kidney, lung, spleen, bone marrow, skin, and, to a lesser extent, brain, heart, and uterus. Small quantities can be detected in hair and nails several months after the main portion of the arsenic has been eliminated from the body [160]. Inorganic arsenicals do not cross the blood – brain barrier but can pass across the mammalian placental membrane [161].

Distribution. After absorption, arsenic is distributed via the bloodstream to most tissues of the human body, preferring the liver, kidney, lung, intestinal wall, spleen, and heart, where it binds primarily to the SH groups of tissue proteins. Furthermore, it is incorporated into hairs and nails, and this can be used for the detection of an exposure to arsenical materials in the past. Arsenic passes the blood – brain barrier only in small amounts. It is incorporated into bones, where it replaces phosphorus and may remain for years [162].

Metabolism. Most arsenic compounds – trivalent or pentavalent, inorganic or organic – are transformed to an arsenic oxide form, which can react readily with proteins, especially with those containing two vicinal mercapto groups, thus forming stable cyclic structures. The inhibition of essential enzymes is considered to be the first step of cell damage [159]. The high affinity of the oxoarsenic moiety for the vicinal mercapto groups of 2,3-dimercapto-1-propanol [*59-52-9*] (BAL, British Anti Lewisite) and of 2,3-dimercapto-1-propanesulfonic acid [*74-61-3*] is used successfully in arsenic poisoning therapy to enhance excretion.

Excretion of arsenicals occurs mainly via urine, to a smaller extent via the feces [163], and by loss of hair and skin shedding. After the administration of a single dose, the concentration of arsenic in liver and kidney starts to decrease only after 24 h [163]. The concentration of arsenic in urine of unexposed persons is between zero and 0.22 mg/L, after industrial exposure between 0.04 and 0.9 mg/L [164]. After inhalation of arsenic dust, the excretion of methylated arsenic could be observed [165]; traces of arsenic can be exhaled as trimethylarsine [166].

Acute Toxicity. Arsenic poisoning mostly occurs by ingestion of inorganic trivalent compounds such as arsenic trioxide. The smallest doses of As_2O_3 reported to be fatal after ingestion are 70 – 180 mg [160]. Symptoms which can occur within a few minutes or after a delay of several hours are vomiting, diarrhea, damage of the intestinal tract, muscular cramps, facial edema, cardiac abnormalities, dehydration, and – as a consequence – shock. The inhalation of irritant arsenic compounds, such as arsenic trichloride or arsenical war gases, causes cough, dyspnea, pain in the chest, severe damage to the respiratory tract, headache, general weakness, nausea, vomiting, and colic diarrhea. Airborne dusts often result in irritation of exposed skin and mucous membranes such as bronchitis, conjunctivitis, laryngitis, and dermatitis [167]. Arsenic trichloride may be absorbed through the skin with fatal consequences [168].

Chronic Toxicity. Chronic arsenic poisoning can be caused by intake of food and water contaminated with arsenicals or by inhalation of airborne dusts during long-term occupational exposure, mainly in smelting plants of ores containing arsenic, insecticide factories, and among vineyard workers, even many years after termination of exposure. Symptoms of these chronic poisonings were symmetrical palmar and plantar hyperkeratosis, white striae of the finger nails, cardiovascular manifestations, myocardial ischemia, hypertension, liver dysfunctions, hematological changes, and vascular disorders resulting in gangrenes of the lower extremities (blackfoot disease). A variety of severe symptoms is treated below.

Skin lesions are frequently observed, e.g., in the production of insecticides [169] and in copper ore smelting plants [170]. Typical symptoms are hyperkeratosis, warts, melanosis, contact dermatitis, eczematoid features of varying degrees of severity, and vascular lesions. Hyperkeratosis often is characterized by thickening, drying, and cracking of the skin [171]. Arsenical melanosis is also a common sign after long-term exposure and can occur on the chest, abdomen, scrotum, and back. Further characteristic symptoms are depigmentation (leukodermia) of pigmented areas and white striae of the fingernails [172].

Effects on mucous membranes are conjunctivitis with swelling and pain, keratoconjunctivitis (resulting from exposure to the insecticide calcium arsenate, $Ca_3(AsO_4)_2$), irritation of the pharynx and bronchial passages, and irritation of the nose resulting in acute and chronic rhinitis. Among copper smelter workers, perforation of the nasal septum has been commonly observed [173].

Peripheral neuritis, with such symptoms as pain, difficulties in walking, burning and tenderness in the affected limbs, and later on severe weakness in both legs and feet, has been described after long-term exposure to arsenate dusts [171]. In contrast to the peripheral neuritis caused by lead, the arsenic-caused neuritis is painful; the nerves of these patients show neuronal degeneration [160]. Further symptoms, observed especially in cases of severe chronic intoxications, are headache, aphasia, drowsiness, disorientation, and changes in the personality.

Liver damages, especially liver cirrhosis, have been observed, e.g., in vintagers who used arsenical herbicides [174] and after long-term consumption of arsenic-contaminated homemade wine [175]. These liver disturbances, which often are complicated by the additional occurrence of chronic hepatitis, ascites, and enlarged liver, are probably not due to skin contact with or inhalation of arsenicals, but to ingestion of contaminated wine. The occurrence of liver damage among industrial workers is reported to be less frequent [167].

Circulatory system symptoms after chronic arsenical poisoning are abnormalities in the electrocardiogram [176] indicating a toxic myocardial effect, peripheral vascular disturbances, gangrene of the extremities, atrophic acrodermatitis, endoangitis [177], and the so-called blackfoot disease [178]. *Gastrointestinal* disturbances are less common among workers with long-term exposure to arsenicals [179]. During chronic intoxication by ingestion, digestive disturbances, nausea, vomiting, and loss of appetite are occasionally reported. *Hematological changes* are also less common in chronic poisoning after industrial airborne exposure. Symptoms like moderate anemia, leucopenia, and thrombocytopenia have been observed after long-term ingestion of inorganic arsenicals. However, these symptoms disappeared 2 – 3 weeks after termination of the arsenic ingestion [180].

Cancer. Workers in smelters or in insecticide factories exposed to arsenic trioxide have a significantly higher risk of lung cancer in comparison to persons not exposed , [182]. A significant excess of oral and pharyngeal cancer could be noticed among male textile workers in England and Wales engaged in fiber preparation [183]; this excess could be traced to arsenic-containing disinfectants used on sheep. Skin cancer as a result of ingesting of contaminated water, with multifocal lesions over the entire body, occurred in Cordoba, Argentina , Antofagasta, Chile , and in Taiwan [186]. The development of other types of tumors related to long-term exposure by ingestion, inhalation, or dermal contact has been observed frequently; however, in these cases the relationship between arsenic exposure and development of tumors could not be confirmed as yet unequivocally [164]. Arsenic should probably be considered as a cocarcinogen [187], [188], since it is able to inhibit DNA-repair enzymes but does not show mutagenicity [189].

Mutagenicity. The mutagenic action of inorganic and organic arsenicals has been tested on microorganisms (DNA damage in *Bacillus subtilis*) [190], Drosophila (increase in crossing-over frequencies) [191], and mammalian cells in vivo and in vitro. A significant increase of chromosomal aberrations could be demonstrated as a result of contact with arsenicals in lymphocytes from peripheral blood [192] and in fibroblast cultures of humans [193].

Reproductive Toxicity. *Teratogenic effects* of disodium arsenate [*7778-43-0*] , such as exen-

Table 14. Toxicological data of arsenic and some arsenic compounds

Compound	CAS registry number	Toxicol. parameter	Dose	Species	Route	Reference
Arsenic	[*7440-38-2*]	LDLo	20 mg/kg	rat	intramusc.	[212]
Arsenic acid, hemihydrate	[*7774-41-6*]	LD_{50}	6 mg/kg	rabbit	i.v.	[213]
Arsenic pentoxide	[*1303-28-2*]	LD_{50}	55 mg/kg	mouse	oral	[214]
Arsenic trichloride	[*7784-34-1*]	LDLo	100 mg/m^3, 1 h	cat	inhal.	[215]
Arsenic trifluoride	[*7784-35-2*]	LDLo	2000 mg/m^3, 10 min	mouse	inhal.	[216]
Arsenic trioxide	[*1327-53-3*]	LD_{50}	45 mg/kg	mouse	oral	[214]
		LD_{50}	20 mg/kg	rat	oral	[217]
		LDLo	4 mg/kg (as As)	rabbit	i.v.	[213]
Arsine	[*7784-42-1*]	TCLo	3 mL/m^3	human	inhal.	[160]
		LCLo	25 mL/m^3, 30 min	human	inhal.	[218]
		TCLo	93 µL/m^3	human	inhal.	[219]
Calcium arsenate	[*7778-44-1*]	LDLo	50 mg/kg	rabbit	oral	[220]
Disodium arsenate	[*7778-43-0*]	LDLo	30 mg/kg	rat	i.p.	[221]
Disodium arsenate, heptahydrate	[*10048-95-0*]	TDLo	43 mg/kg	mouse	i.p.	[222]
Lead arsenate	[*7645-25-2*]	LD_{50}	100 mg/kg	rat	oral	[223]
		LDLo	75 mg/kg	rabbit	oral	[220]
Sodium metaarsenite	[*7784-46-5*]	TDLo	40 mg/kg	mouse	oral	[224]

cephaly [194], cleft palate and lip, microanophthalmia, genitourinary abnormalities, ear deformities, and renal agenesis, were observed in hamster fetuses [195–197]. In the case of a 17-year-old girl, the ingestion of arsenic during the third trimester of her pregnancy caused the death of her baby (1100 g!) 11 h after birth; liver, kidney, and brain of the baby contained high concentrations of arsenic [198]. Among employees and persons living near a smelter, a significant decrease of the birth weight of the offspring, an increased frequency of spontaneous abortions, and a higher rate of malformations of the children born were observed [199], [200].

In animal studies, an effect of arsenic on *fertility* in males or females has not been demonstrated so far [201].

Arsine. Acute poisoning with arsine [*7784-42-1*], AsH_3, which is rather frequent among industrial workers as compared to poisoning with other arsenicals, results in general malaise, nausea, vomiting, abdominal cramps, coppery skin pigmentation, red staining of the conjunctiva [202], and leucocytosis [203]. A most characteristic symptom of acute arsine poisoning is rapid hemolytic anemia, which results in hemoglobinuria, decreased hemoglobin level, jaundice, and after 2 – 24 h, shock, oliguria, and anuria due to blockade of renal tubuli [204] by membrane residues of red blood cells. Other symptoms are pyrexia, edema of the lungs, delirium, and coma. Death after few days is mostly due to myocardial failure. In all cases of arsine poisoning an elevation of the T-wave in the electrocardiogram can be noticed. Depending on the severity of the intoxication, the time of the appearance of symptoms may vary between a few minutes and 24 h.

Chronic arsine poisoning shows a delayed onset of symptoms mentioned above, and in some cases peripheral neuritis [205], hemoglobin levels as low as 32 g/L, and basophilic stippling of red blood cells [206] have been observed.

Organic Arsenic Compounds. Compounds of the type $RAsCl_2$, R_2AsCl, and R_2AsCN have been developed and partly used as war gases during World War I. Examples are dichloro-2-chlorovinylarsine [*541-25-3*], lewisite, $ClCH{=}CHAsCl_2$, chlorodiphenylarsine, Clark I D., $(C_6H_5)_2AsCl$, and cyanodiphenylarsine, Clark II D., $(C_6H_5)_2AsCN$. They generally exert a high toxicity, which is directed against skin, eyes, respiratory tract, gastrointestinal tract, and central nervous system, showing symptoms similar to those described above [207].

Toxicological Data and Exposure Limits. Toxicological data of commonly used arsenicals are summarized in Table 14. The MAK value of arsine is 0.2 mg/m^3 (0.05 ppm) [208]. The MAK values for various arsenicals such as oxides and arsenic acids and their salts have not been established because these compounds have

been proved to cause malignant tumors in humans [208]. According to the IARC evaluation, arsenic and its compounds are carcinogenic to humans (Group I) [209], whereby the skin and lungs are proven target organs, while the liver, hematopoetic system, gastrointestinal tract and kidney are suspected target organs. The TRK values in Germany for all compounds with the exception of arsine is 0.1 mg/m^3 (as As) [208]. The unit risk value representing the additional relative carcinogenic risk caused by AS (based on life-long exposure to 1 µg As/m^3) has been established as 0.004 by the LAI [210].

In the United States, the TLV-TWA for arsenic and its compounds is 0.2 mg/m^3; the value for arsine is 0.2 mg/m^3 (0.05 ppm) [211]; in the United Kingdom, the MEL is 0.1 mg/m^3 (as As).

Abstract

The article contains sections titled:

1. Introduction
2. Organic Pigments
3. Inorganic Pigments
3.1. White Inorganic Pigments
3.2. Colored Inorganic Pigments
3.3. Black Pigments
3.4. Fillers
4. Dyes for Silk Painting
5. Binders
6. Quality Factors
7. Commercially Available Artists' Colors and Materials
7.1. Oil Colors
7.2. Acrylic Paints
7.3. Watercolor (Aquarell)
7.4. Pastels
7.5. Gouache and Distemper (Tempera)
7.6. Powdered Pigments
7.7. Silk Paints
7.8. Paints for Graphic Techniques
7.9. Other Artists' Materials

Artists'; colors represent just a small sector of the paint industry, the total invoiced sales in Europe were about 222.7 × 10^6 € in 2004, the production of artists' colors in Germany amounted to about 4180 t with a value of 67.1 × 10^6 € in 2004. Artists' colors are mixtures of three major components: pigments, binders, and fillers.

Pigments determine the hue, hiding power, and tinting strength of artists' colors. Binders enable the pigments to adhere to the substrate. Fillers can influence optical properties such as whiteness and hiding power, rheological behavior, mechanical properties, and resistance to weathering and chemicals.

The commercially available artists' colors and materials are the following types: oil colors, acrylic paints, watercolors, pastels, gouache and tempera, powdered pigments, silk paints, paints for graphic techniques, and others artists' materials such as primers and varnishes.

1. Introduction

Artists' colors represent just a small sector of the paint industry. In 2004 the production of artists' colors in Germany was about 4180 t with a value of 67.1 × 10^6 € and the total invoiced sales in Europe amounted to about 222.7 × 10^6 € [1], [2]. Artists' colors are mixtures of three major components: pigments, binders, and fillers.

Pigments are defined as colored, black, white, or fluorescent particulate organic or inorganic solids which usually are insoluble in, and essentially physically and chemically unaffected by, the vehicle or substrate in which they are incorporated. They alter appearance by selective absorption and/or scattering of light. Pigments retain a crystal or particulate structure throughout the coloration process [3], [4]. Pigments determine the hue, hiding power, and tinting strength of artists' colors. Natural inorganic pigments have been known since prehistoric times. The principal pigments used were based mainly on iron and manganese oxides, found in the soil as colored muds. Natural ocher was used in the Ice Age as a coloring material. Around 2000 B.C., natural ocher was burnt, sometimes in mixtures with manganese ores, to produce red, violet, and black pigments for pottery. Arsenic sulfide as the first clear yellow pigment, and ultramarine (lapis lazuli) and Egyptian blue cobalt aluminum spinel were the first blue pigments. Terra verte and malachite were the first green pigments. The first modern synthetic pigment was Prussian blue (1704), followed by the synthesis of cobalt blue (1777), Scheele's green, and chrome yellow (1778) [5]. The synthetic materials provide the artist with colorants that are relatively pure and reproducible in color and particle size.

A detailed description of the properties, production and uses of inorganic and organic pigments is given in ⟶ Pigments, Inorganic and ⟶ Pigments, Organic.

Pigments and dyes are categorized according to their generic name and chemical constitution in the Colour Index [6]. Important pigment properties include tinting strength, light fastness, weather resistance, hiding power, transparency, shade, dispersibility, and chroma (⟶ Pigments, Inorganic).

In former times, whole egg, egg yolk, and egg white were used as *binders*. In the Middle Ages it was already known that egg yolk act as emulsifier with oils or dissolved resins. Binders enable the pigments to adhere to the substrate.

Fillers can influence optical properties such as whiteness and hiding power (e.g., synthetic silicates and blanc fixe as partial replacements for white pigments), rheological behavior, mechanical properties, and resistance to weathering and chemicals.

Pigment Blue 16	74100	phthalocyanine	***
Pigment Blue 60	69800	indanthrone	***
Pigment Green 7	74260	copper phthalocyanine	***
Pigment Green 36	74265	copper phthalocyanine	***

[a] see Table 5.

Azo pigments (⟶ Pigments, Organic – Azo Pigments*)* cover mainly the range of yellow, orange, red, violet, and brown shades.

Examples for monoazo pigments are C.I. Pigment Yellow 1, Pigment Orange 5, Pigment Red 112, Pigment Red 176, and disazo pigments include C.I. Pigment Yellow 83, Pigment Orange 34, and Pigment Red 144 (Table 1).

Polycyclic pigments used in artists' colors are:

- Phthalocyanine pigments (e.g., Pigment Blue 15 : 3, Pigment Green 36)
- Quinacridone pigments (e.g., Pigment Red 122, Pigment Violet 19)
- Perylene and perinone pigments (e.g., Pigment Violet 29, Pigment Orange 43)
- Isoindolinone and isoindoline pigments (e.g., Pigment Yellow 110)
- Anthrapyrimidine pigments (e.g., Pigment Yellow 108) Diketopyrrolopyrrole pigments (e.g., Pigment Red 254).

[Top of Page]

3. Inorganic Pigments

All inorganic pigments contain heavy metal constituents with the exception of titanium dioxide, carbon black, and ultramarine pigments.

Table 2 lists inorganic pigments used for artists' colors.

Table 2. Inorganic pigments used for artists' colors [a]

C.I. name	C.I. number	Common name	Composition
Pigment White 1	77597	lead white	$2PbCO_3 \cdot Pb(OH)_2$
Pigment White 4	77947	zinc white	ZnO
Pigment White 6	77811	rutile	TiO_2
Pigment White 18	77220	chalk	$CaCO_3$
Pigment White 19	77002	clay	$Al_2O_3 \cdot SiO_2$
Pigment White 22	77120	blanc fixe	$BaSO_4$
Pigment White 24	77002	alumina hydrate	$Al(OH)_3$
Pigment Yellow 35	77205	cadmium zinc sulfide	$(Cd,Zn)S$
Pigment Yellow 42	77492	synthetic hydrated iron oxide	$FeOOH$
Pigment Yellow 53	77788	nickel antimony titanium yellow (rutile)	$(Ti,Ni,Sb)O_2$
Pigment Yellow 184	-	bismuth vanadate/molybdate	$4BiVO_4 \cdot 3Bi_2MoO_6$
Pigment Orange 20	77202	cadmium sulfide/selenide	$Cd(S,Se)$
Pigment Red 101	77491	synthetic oxide	Fe_2O_3
Pigment Red 108	77202	cadmium sulfide/selenide	$Cd(S,Se)$
Pigment Brown 7	77491	sienna/umber	Fe_2O_3

Pigment Brown 24	77310	chromium antimony titanium (rutile)	$(Ti,Cr,Sb)O_2$
Pigment Brown 33	77503	zinc iron chromite brown (spinel)	$(Zn,Fe)(Fe,Cr)_2O_4$
Pigment Violet 14	77360	cobalt violet phosphate	$CO_3(PO_4)_2$
Pigment Violet 15	77007	ultramarine red/violet	Na,Si,Al,S
Pigment Violet 16	77742	manganese violet	$(NH_4)Mn(P_2O_7)$
Pigment Blue 27	77510	Prussian blue	$NH_4[Fe(II)Fe(III)(CN)_6] \cdot H_2O$
Pigment Blue 28	77346	cobalt blue (spinel)	$CoAl_2O_4$
Pigment Blue 29	77007	ultramarine blue	Na,Si,Al,S
Pigment Blue 33	77112	manganese blue	$BaMnO_4/BaSO_4$
Pigment Blue 35	77368	cerulean blue	Co_2SnO_4
Pigment Blue 36	77343	cobalt chromite blue (spinel)	$Co(Al,Cr)_2O_4$
Pigment Green 17	77288	chrome oxide green	Cr_2O_3
Pigment Green 18	77289	viridian	$Cr_2O_3 \cdot 2H_2O$
Pigment Green 19	77335	cobalt nickel zinc titanite green	$(Co,Ni,Zn)_2TiO_4$
Pigment Green 23	77009	green earth	iron(II) silicate with clay
Pigment Green 26	77344	cobalt chromite green (spinel)	$CoCr_2O_4$
Pigment Green 50	77377	cobalt titanate green (spinel)	Co_2TiO_4
Pigment Black 7	77266	carbon black	almost pure C
Pigment Black 9	77267	bone black	$Ca_3(PO_4)_2/C$
Pigment Black 11	77499	black iron oxide	Fe_3O_4

[a] All pigments have *** lightfastness (see Table 5).

3.1. White Inorganic Pigments

The largest group of the inorganic pigments are the white pigments, and they are among the most important in the artists' palette. The four major white pigments in use today are titanium dioxide (TiO_2, C.I. Pigment White 6), zinc white (ZnO, C.I. Pigment White 4), blanc fixe ($BaSO_4$, C.I. Pigment White 22), and white lead [$Pb(OH)_2 \cdot 2\ PbCO_3$, C.I. Pigment White 1].

White lead dates back to the early Greeks and was, until recently, the principal white oil-colors pigment because of its almost ideal properties when mixed with oil. White lead may discolor on exposure to hydrogen sulfide. Nowadays, especially because of the toxicity, the use of lead white is limited to restoration only.

Titanium dioxide (⟶ Pigments, Inorganic – Titanium Dioxide) occurs in nature in the modifications rutile, anatase, and brookite. Rutile and anatase are produced industrially as the most important pigments in terms of quantity [7]. Titanium dioxide (C.I. Pigment White 6) is of outstanding importance as a white pigment because of its scattering properties, its chemical stability, its biological inertness, and its lack of toxicity. The pigment is frequently coated with colorless organic or inorganic compounds of low solubility to improve its weather resistance, lightfastness, and dispersibility.

Zinc white is a fine white powder, which is amphoteric; it reacts with organic and inorganic acids, and also dissolves in alkalis to form zincates [8]. Acute toxicity: rat, oral, LD_{50} > 15 000 mg/kg [9].

Barium sulfate (blanc fixe) is of lower hiding power than white lead, but has resistance to hydrogen sulfide [10]. In artists' colors barium sulfate is often used to adjust the consistency of the liquid paint.

3.2. Colored Inorganic Pigments

Natural Earth Pigments. Today natural earth pigments used as artists' pigments are green earth (ferrous silicate with clay, C.I. Pigment Green 23) and natural iron oxides. Naturally occurring iron oxides and iron hydroxides have been used as pigments since prehistoric times. They were also used as colorants by the Egyptians, Greeks, and ancient Romans. Of the natural iron oxide pigments, hematite (α-Fe_2O_3) attained economic importance as a red pigment, goethite (α-FeOOH) as a yellow pigment (C.I. Pigment Yellow 43), and the umbers and siennas as brown pigments (C.I. Pigment Brown 7). Their poor tinting strength and less saturated color shade are due to their low purity and broader particle size distributions compared to synthetic pigments. Frequently clays or silica are present in natural earth pigments.

Metal Oxides. Synthetic iron oxide pigments are by far the most important group of colored pigments. They include α-FeOOH (iron oxide yellow, C.I. Pigment Yellow 42), α-Fe_2O_3 (iron oxide red, C.I. Pigment Red 101), and Fe_3O_4 (iron oxide black, C.I. Pigment Black 11). Synthetic iron oxides are produced under controlled conditions by a number of manufacturing processes. They are chemically purer and, because of their higher iron content, exhibit greater brightness than naturally occurring oxides. Depending on their crystalline structure and other physical parameters, iron oxide pigments range in color from various shades of red through ocher to black.

Chromium(III) oxide, which forms the basis of chromium oxide pigments, crystallizes in a corundum lattice [11]. Chromium oxide green pigments (Cr_2O_3, C.I. Pigment Green 17) contain only trivalent chrome. Acute toxicity: rat, oral, LD_{50} > 10 000 mg/kg [9]. Chromium oxide pigments yield a fairly dark olive-green shade. They are largely inert chemically and therefore possess good resistance properties.

Complex Inorganic Color (CIC) Pigments. The term “complex inorganic color pigment” refers to the fact that such pigments are a homogenous chemical phase and replaces the formerly used term “mixed-phase metal oxide pigment”, which gave the false impression that they are mixtures.

Nickel antimony titanium yellow $(Ti,Ni,Sb)O_2$ (C.I. Pigment Yellow 53, acute toxicity: rat, oral, LD_{50} > 5000 mg/kg [9]) and chromium antimony titanium yellow $(Ti,Cr,Sb)O_2$ (C.I. Pigment Brown 24, acute toxicity: rat, oral, LD_{50} > 5000 mg/kg [9]) are rutile pigments. The rutile lattice of titanium dioxide absorbs nickel oxide or chromium(III) oxide as coloring components and antimony(V) oxide to maintain an average cation valency of four.

The cobalt blue pigments are pigments with a spinel structure obtained by partial or complete replacement of metal ions of the $MgAl_2O_4$ spinel by cobalt and chromium (e.g., $CoAl_2O_4$, C.I. Pigment Blue 28, acute toxicity: rat, oral, LD_{50} > 10 000 mg/kg [9]). Incorporation of cobalt and nickel in the inverse titanium spinels MgO_2TiO_4 and Zn_2TiO_4 produces cobalt green pigments (e.g., Co_2TiO_4, C.I. Pigment Green 50, acute toxicity: rat, oral, LD_{50} > 10 000 mg/kg [9]).

All these pigments are chemically and thermally very stable and have outstanding lightfastness and resistance to temperature, chemicals and weathering.

Cadmium Pigments. All cadmium pigments are based on cadmium sulfide (CdS, C.I. Pigment Yellow 37) and exist in a highly stable hexagonal crystal form. Inclusion of zinc yields greenish yellow pigments [(Cd, Zn)S, C.I. Pigment Yellow 35] and inclusion of selenium changes the shades to orange [Cd(S, Se), C.I. Pigment Orange 20], red [Cd(S, Se), C.I. Pigment Red 108] and bordeaux. The terms cadmium yellow and cadmium red have become synonymous with brillant yellow and red shades. Especially because of their excellent lightfastness, cadmium pigments are appreciated as artists' colors. Acute toxicity: rat, oral, LD_{50} > 5000 mg/kg [9].

Ultramarine Pigments. Ultramarine blue is the synthetic equivalent of the naturally occurring semi-precious stone lapis lazuli. The unique blue color is due to polysulfides within a sodium aluminum lattice, $Na_6Al_6Si_6O_{24}(NaS_n)$ (n = 2 – 4). Violet (C.I. Pigment Violet 15) and pink (C.I. Pigment Red 259) ultramarines are derived from ultramarine blue (C.I. Pigment Blue 29) by further oxidation and ion exchange and have a very similar structure.

Ultramarines have excellent lightfastness and heat stability and, apart from their sensitivity to acid, good chemical resistance.

Manganese Violet Pigments. Manganese violet pigments are manganese ammonium pyrophosphates, and are red-shade, bright, clean violets ($NH_4MnP_2O_7$, C.I. Pigment Violet 16). Manganese violets have excellent lightfastness, good heat stability and, apart from their sensitivity to alkalis, good chemical resistance.

The excellent lightfastness and purity of shade, both in mass tone and pale shades, makes manganese violet ideal for use in artists' colors.

Iron Blue Pigments. The term iron blue pigment (C.I. Pigment Blue 27) has largely replaced a great number of older names (e.g., Prussian blue, Berlin blue, Milori blue). These names usually denoted insoluble pigments based on microcrystalline Fe (II)/Fe(III) cyano complexes with the formula $M^IFe^{II}Fe^{III}(CN)_6 \cdot H_2O$, where M^I is potassium, ammonium, or sodium, of which potassium is preferred because it produces excellent hues [11]. Acute toxicity: rat, oral, LD_{50} > 5000 mg/kg [9].

3.3. Black Pigments

Carbon black pigments (C.I. Pigment Blacks 6 and 7) are produced by thermal-oxidative dissociation of aromatic oils, e.g., by the lamp black, furnace black, and gas black processes (⟶ Carbon – Production Processes). A further black pigment used as an artists' color is bone black (C.I. Pigment Black 9), which essentially consists of carbon (10 – 20 %) and $Ca_3(PO_4)_2$ (70 – 80 %) [12].

3.4. Fillers

Fillers are used to modify or influence certain physical properties of paints. Organic pigments with high tinting strength often need a filler to adjust the consistency, hue, and hiding power.

Fillers of importance for artists' colors are natural barium sulfate (baryte), precipitated barium sulfate (blanc fixe), aluminum hydroxide, calcite, precipitated calcium carbonate, and clays.

[Top of Page]

4. Dyes for Silk Painting

Dyes as artists' colors are mainly used to color textiles, especially silk. Silk painting as a technique for producing exquisite articles of clothing and works of art is a tradition that dates back thousands of years, particularly in Asia.

Table 3 gives a list of dyes that are used for silk painting.

Table 3. Dyes for silk painting

C.I. name [a]	C.I. number	Chemical class	Reactive System	Lightfastness, 1/1 S.D. [b]
AY 61		azo		5 – 6
AO 95		disazo		4 – 5
ABr 413		azo metal complex		6 – 7
AB 83	42660	triphenylmethane		3 – 4
AG 81		anthraquinone		6 – 7
AB 222		azo (1 : 2 Cr complex)		7
BY 104		azo		6 – 7
RY 27		monoazo		6
RR 123		monoazo		4
RV 5		monoazo (metal complex)	vinylsulfonyl	6 – 7
RB 29		anthraquinone		5 – 6
RG 21		phthalocyanine		7
RB 113		azo (1 : 2 metal complex)	monochlorotriazinyl	6
DY 157	13965	monoazo		3 – 4
DB 199	sim. to 74190	phthalocyanine		7
DE 1168		azo		5

[a] First letter: A = acid, B = basic, R = reactive, D = direct; second letter: B = blue, Bl = black, Br = brown, G = green, O = orange, V = violet, Y = yellow.
[b] S.D. = standard depth (DIN 53235)

Reactive Dyes. Reactive dyes undergo true chemical bonding with the silk during fixing. Reactive dyes commonly used in silk dyes either contain sulfatoethylsulfone (SES) groups or organo-halogen anchor groups (mono- and dichlorotriazine groups, difluorchlorotriazine groups). With SES-type dyes, the reaction with the silk takes place with a vinylsulfone group that is formed from the SES group during thermal or alkaline fixing and quickly reacts with the amino groups of the silk fiber. Chloro-organic anchor groups react directly with the fiber, producing chloride as a reaction byproduct.

Acid Dyes. Acid dyes contain one or more anionic sulfonate and/or carboxylate groups and have high affinity towards wool and silk. Fixing mainly results from ionic reactions which take place with the basic or cationized groups in the fibers. Acid dyes can contain various classes of chromophores (azo, anthraquinone, triphenylmethane). Acid metal complex dyes are used for darker shades or where particularly high wetfastness properties are required and for the manufacture of silk screen dyes.

Direct Dyes. Direct (substantive) dyes are highly water soluble anionic dyes based on various classes of chromophores. They are mainly used to color cellulose-based fibers. Direct dyes are fixed onto silk by ionic reaction and hydrogen bonding.

[Top of Page]

5. Binders

For use as a paint or artists' colors pigments must be incorporated into a liquid or pastelike phase which allows it to adhere to a surface.

Besides modern synthetic binders classical, natural binders are used for artists' colors. The thinning power and the rheological characteristics of the paint are important for certain techniques like impasto or thin layer, and they depend on the type of vehicle [13]. Binders which are transparent and colorless and impart high fastness to all physical properties are preferred for artists' colors.

The binder incorporates the pigments and determines the physical and optical properties of the generated film. Physical properties are film strength, elasticity, gloss, adhesion to the ground, and resistance to light, weather, alkali, acid, and heat. Optical characteristics are transparency, hue, and refractive index, which determine the opacity of the pigment.

A paint generally consists of three components:

1. The film-former, a chemical that dries by polymerization, physically by evaporation of solvents, or by oxidation in air.
2. The solvent in which all other materials are dissolved or suspended if the binder is not liquid.
3. Small quantities of additives that perform special functions like accelerating or hindering functions, optimizing drying processes, optimizing rheology and surface properties, and controlling the open time.

Combinations of film-formers are also used. For example, the type binder for tempera paints is a combination of oil and

water-soluble gum arabic (or casein) emulsified with the aid of an emulsifying agent.

Table 4 lists types of binders which are used for artists' colors.

Table 4. Binders for artists' colors

Type of binder	Film former	Solvent	Thinner	Process
Natural wax	beeswax	none		physically
		turpentine	turpentine	evaporation
		white spirit	white spirit	evaporation
Natural drying oil	linseed, sunflower, safflor oil	oil	oil of turpentine, white spirit	chemical reaction with oxygen
Natural resin	dammar, mastic	oil of turpentine, white spirit	oil of turpentine, white spirit	evaporation
	shellac	ethanol	ethanol	evaporation
Synthetic resin	alkyd resins	oil of turpentine, white spirit	oil of turpentine, white spirit	chemical reaction with oxygen
	polymer dispersion	water	water	polymerization
Natural glue	animal-bone, skin, and casein glue	water	water	evaporation
	plant gum arabic and starch glue	water	water	evaporation
Synthetic glue	cellulose ether, carboxymethyl cellulose	water	water	evaporation
Natural mineral	lime, gypsum	water	water	chemical reaction with carbon dioxide (or physically with water); no film is formed
Synthetic mineral	water glass	water	water	chemical reaction with carbon dioxide to give silica; no film is formed

[Top of Page]

6. Quality Factors

The quality of artists' colors and the final fastness of the painting are determined jointly by the binders and pigments.

Pigments differ in their physicochemical and in their optical characteristics. Physically, pigments must withstand light, weather, and heat. Chemically they must resist the action of alkali and acids. To prevent migration, the pigments must be resistant to the binder, this mainly means insoluble in the binder.

Optical properties of pigments are shade, tinting strength, lightfastness, and hiding power. Pigments can fade or darken, mainly under the action of UV radiation, which can break certain chemical bonds or change the molecular constitution. A change in chemical structure means a change of absorption in the visible region of the spectrum and a subsequent loss of tint or change of hue. However, if the pigment absorbs UV light without any change of molecule structure, decomposition of the binder may be prevented [14], [15].

Three systems are used for defining lightfastness. The ASTM standard [16], defines five fastness classes, determined by exposure to xenon lamps or sunlight and color matching. In the blue wool scale method (DIN 53952) a range of eight wool strips are exposed to sunlight or a xenon lamp together with the paint, and after exposure the paint is evaluated according to the change on the wool scale. Colormakers use a star system to indicate the lightfastness of paints to the artist [17].

Table 5 compares the three scales.

Table 5. Comparison of lightfastness scales

ASTM class (D4303/93a)	Star scale	Blue wool scale (DIN 53952)
I	*** highest lightfastness	8 very excellent

		7 excellent
II	** very good lightfastness	7 excellent
		6 very good
III	* sufficient lightfastness	6 very good
		5 good
IV	o little lightfastness	4 quite good
		3 moderate
V		2 little
		1 very little

Opacity depends on the ability of a pigment to scatter light in a paint film. If the pigment does not scatter light, the layer is transparent. If light is strongly scattered, the film is opaque [13].

The light-scattering power of a pigment depends on its particle size and its refractive index relative to that of the medium in which it is dispersed.

[Top of Page]

7. Commercially Available Artists' Colors and Materials

7.1. Oil Colors

Paints made from vegetable oils (drying oils) have been known since the Middle Ages. In the mid-1500s, oil painting on canvas was the standard technique for artists' easel painting. Advantages of these paints include ease of manipulation due to the long open time, the ability to correct the painting after a couple of days, and the wide range of effects that can be produced (transparent to opaque in full range). Colors do not change to any great extent on drying, which takes place by reaction with atmospheric oxygen [15]. Then, the film becomes insoluble in white spirit or turpentine. The drying oil incorporates the pigment particles and forms a rigid and flexible film. The oil also acts as an adhesive, fixing the pigments on the ground. The optical efficacy is shown by the brillancy and the color of the pigments.

The best consistency for oil colors is a smooth, “short and buttery” paste which does not flow of its own accord and is without tacky, stringy, or long characteristics. The brush strokes must be visible in the applied paste.

The drying process of artists' oil colors is influenced by the type of oil and the pigment properties. The proportion of unsaturated fatty acids determines the drying properties. The drying properties increase with increasing content of linoleic and linolenic acids.

Properties of the dried oil color, which are also influenced by the pigment to some degree, include consistency, extent of oxidation, flexibility and hardness, which finally result in durability and stability to the environment and physical or chemical treatment.

Table 6 lists the most common drying oils for oil colors.

Table 6. Percentage fatty acid composition of drying/semi-drying oils used in artist's oil colors

Drying oil	Palmitic/stearic acid	Oleic acid	Linoleic acid	Linolenic acid
Linseed	9	22	17	52
Walnut	8	17	61	14
Soya	14	21	56	8
Safflower	10	13	77	
Poppy seed	10	16	75	
Sunflower	10	28	61	

Dryers influence the drying times of paints by compensating for the varying effects of the pigments. One of the most common dryer is cobalt naphthenate [17]. This dryer is a skin sensitizer, and the presence of more than 1 % of it in oil colors requires health-warning labeling.

Presently, two main types of oil colors are available commercially: traditional colors with drying oils as binders, and resin – oil colors containing dammar, mastic or acrylic resin. Some brands contain beeswax as a stabilizer for increased shelf life, film-forming properties, or consistency.

For further information on the composition of oil colors, see [18].

A new generation of water-miscible oil colors is now on the market. These oil colors can be diluted with water and are

suitable for persons sensitive to solvents. Instead of normal linseed oil, modified oils are commonly used, together with emulsifying agents.

7.2. Acrylic Paints

Artists' colors based on acrylic dispersions were first produced in the 1950s in the United States [20]. They are highly expressive and favored by many contemporary artists. Acrylics are used for impasto and flowing techniques like aquarelle, airbrush, fabric painting, mural painting, silkscreen painting, print making, sculpture, photo retouching, and hard-edge painting. They can be applied to paper, paperboard, canvas, wood, murals, leather, and textiles, which are usually treated with gesso, mediums, or additives. Acrylic paints are produced in various qualities and viscosities in dissolvers, roll mills, or ball mills and available in tubes or jars.

The paints consist of pigments (see Tables 1 and 2), fillers, acrylic dispersions, wetting agents, defoamers, coalescence additives, preservatives, and water [19]. For further specifications of acrylic paints, see [21], [22].

Acrylic dispersions are based on acrylic acid, methacrylic acid and their methyl, ethyl and butyl esters. The most frequently used dispersions for artists' paints contain mainly ethyl and methyl acrylate resins. They can be diluted with water and dry rapidly to a permanent water-insoluble film, which is soluble in certain organic solvents (e.g., dichloromethane).

During the drying process water evaporates and the dispersed acrylic particles coagulate.

This process depends on the minimum film forming temperature, a typical physical property of the resins. Drying temperatures of acrylic paints should not be lower than 8 °C and not exceed 15 – 30 °C [20]. Another important physical property for producers is the glass transition temperature. For mechanism of the coalescence process of acrylic dispersions, see [21].

Acrylic films are durable, flexible, do not discolor, and are easily overpainted. They can be of any thickness and have no tendency to crack. Like water colors, the appearance of the dry film differs from that of the freshly applied paint. Because of the quick drying process all brushes and tools have to be cleaned immediately after use.

An environmental risk of dispersions is posed by their content of emulsifiers. They are classified as slightly water polluting. Liquid paint has to be disposed of as hazardous waste. Preservatives are a human health risk if undiluted, but due to the concentration of 0.2 – 0.3 % in normal use, no health labeling is required.

A special line of acrylic colors is airbrush paint, which is liquid, also based on water, containing either acrylic dispersions or water-soluble acrylic resins and highly dispersed pigments.

7.3. Watercolor (Aquarelle)

Transparent watercolor painting is not associated with any particular period. KOLLER suggested that watercolor painting started in the 1400s [23].

Watercolor is a translucent paint which utilizes the brilliant white of the paper for its whites and pale tints. This definition is not absolutely correct, because the pigments and their typical characteristics influence the properties of the color. The pigments are not normally transparent but are applied in such thinned-out consistency that their effects are nearly as brilliant as those of the naturally transparent pigments. The ability of the paper to absorb and fix pigment particles in its interstices is equally important as the ability of the binder to bind the color to the ground; thus, watercolor is more like a stain [14].

Pigments for watercolors require the highest lightfastness, because there is no other light-absorbing medium on the surface of the paper. Pigments containing lead are not used for the production of watercolors.

Colormakers refer to the transparency and lightfastness of each shade in their product information sheets. For determination and definition of lightfastness, see [24].

SCHINK [25] classified the watercolors as *staining* and *nonstaining* colors. *Staining* colors are pigments of high adhesive power or of extremely fine grain size which stick to the paper or stain it strongly after application. *Nonstaining* colors can be washed off with a moist brush, cloth, or other tools. These pigments have weak adhesive power and good mixing properties with other pigments on the paper. Watercolors consist of finely dispersed pigments in a watery solution of gum arabic and/or dextrin, wetting agents (e.g., oxgall), and fillers. Sugar, glycerol, glucose syrup or different types of nontoxic glycols are used as softeners.

The combination of natural gum and softener determines the solubility of solid watercolors in pans. This system, especially the binder and fillers, guarantees the free flow of the paint, good wetting properties, and a stable pigment dispersion at high dilution [14]. Preservatives are added to prevent the growth of microorganisms.

The dispersing process is normally carried out in roll mills, which allow a high degree of dispersion of the pigment.

Solid watercolors in pans are manufactured by pouring the liquid mass into pans followed by drying or by extrusion of a high-viscosity paste, which is cut to shape.

7.4. Pastels

Compared to other painting mediums, pastels allow very pure and simple paintings — very similar to painting with pure pigments on a rough ground. The pigments adhere solely by adhesion without a binder.

Pastels are made from a colored watery paste, which is kneaded and then molded into a crayon shape. Only a weak binding

medium is used. To obtain a moldable paste, the pigments are ground together with clay or light spar and a solution of the binder.

Pastels are defined as soft or hard. Commonly gum tragacanth, gum arabic, sugar, gelatin, casein, aqueous oat extracts, and wax emulsions are used as binders.

Lead and cadmium pigments should not be used in pastel sticks due to the dust that can be generated during application and to avoid skin contact when artists blend the colors with their fingers.

The range of a complete pastel series starts with pure colors, followed by lighter and darker shades. FLATTMANN [26] gives an example of such a series of shades:

M: 80 % white added
K: 60 % white added
H: 40 % white added
F: 15 % white added
D: the pure color
C: 15 % black added
A: 40 % black added

The effect of pastel painting is achieved by diffusion of the light scattered from the surface. This results in an optical problem on fixation of the painting. Fixation reduces the opacity and diffusion of the surface-scattered light and so the painting becomes darker. The use of titanium white or zinc white in combination with the colored pigments, however, compensates for this process and allows easier formulation of the paint [26].

Fixatives for pastels, as described in [14], are ca. 1 – 2 % solutions of a natural resin, like mastic, dammar, Venetian turpentine, or shellac in highly volatile solvent such as diethyl ether, ethanol, or white spirit. Commercially available fixatives are solutions of yellowing-resistant ketones or acrylic resin in alcohol for spray application. In some cases, aqueous fixatives such as gelatin or casein can also be used.

7.5. Gouache and Distemper (Tempera)

Gouache and distemper are described together here because of their similar applications and compositions. The term *tempera* (from the Italian *temperare* = mixing) refers to thin, watery colors based on egg white or gum arabic, as well as for colors with egg yolk as binder [27]. Depending on the nature of the emulsion of aqueous binders and vegetable oils, tempera varies from opaque to transparent. The use and formulation of tempera in the early 1900s is referred to in [28], [29].

Tempera colors are insoluble, but this does not mean that they are absolutely waterproof. This permits overpainting without changing the underlying layers. Under completely dry conditions tempera colors are water-resistant. In contrast to oil paintings, which may become yellow or darken in course of time, tempera paintings remain unchanged. Properly painted tempera pictures are less likely to crack with age than oil paintings, but there are some other restrictions due to the inflexibility of the film of a tempera painting [13].

Tempera binders consist of linseed, sunflower, poppy, or other vegetable oils and/or solutions of dammar, mastic, or Venice turpentine emulsified in watery solutions of gum arabic, casein, or simply egg yolk or whole egg. Oil in water emulsions are also used.

Casein/oil tempera emulsions tend to turn yellow quickly; this can be avoided by adding saponified wax or Venice turpentine instead of oil [13]. Beeswax can also be used as a paste in white spirit (hydrophobic phase) or as emulsifying agent in saponified form [30]. Typical additives in tempera paints are further spikenard, clove oil, nontoxic glycols, emulsifying agents and preservatives. Glycerol and castor oil act as plasticizers. Tempera paints are produced in ball mills, dissolvers, or roll mills.

Tempera paints are applied to paper, paperboard, canvas, and wood which has been pretreated with a primer. Tempera painting is still often combined with oil painting, most like a preliminary coating (imprimatura) [14], [27]. The grounds are based on chalk, marble, or light spar as well as pure glue or half-oil grounds [30]. Tempera painting can be with or without varnish.

Gouache (from the Italian *guazzo* = puddle) paints consist of glue binder, pigment, opaque fillers, and water. They are opaque watercolors with the same basic binding medium and mainly the same pigments as aquarelles. Opacity is obtained by adding white pigments or calcium carbonate [31].

In the late 1700s in England, aquarelles was called “watercolor” and clear gouache was called “body color” [32]. In the 1700s and 1800s gouache painting played an important role in European art, especially in Italy and France [33]. Gouache paint is applied in thicker layers than aquarelles. The binding medium contains softeners, but the risk of cracking of the painting cannot be avoided, neither with synthetic resins (polyvinyl compounds) nor with gum arabic and dextrin.

Finger paints for children are water-miscible and nonwaterproof-drying colors which can be easily removed from paper and other grounds with water and tissues. Finger paints are subject to government regulations and must not contain toxic substances. A positive list of applicable binders, fillers, organic solvents, detergents, and embittering agents is part of European standards. Pigments and preservatives must be permitted for use in food or cosmetics. The migration of certain elements (Sb, As, Ba, Cd, Cr, Pb, Hg, and Se) is also restricted [34].

7.6. Powdered Pigments

The use of pure powdered pigments is one of the oldest methods of artwork. All pigments used in artists' colors are commercially available and can be used with different binders for self-made artists' colors.

Powdered pigments are mainly used in mural painting (fresco) and encaustic painting. There are three different mural-painting techniques [13]. The traditional fresco buon process involves painting on a wet, freshly prepared lime-plaster wall, with pigments dispersed in water only. The pigment particles are cemented on the lime surface in the same manner as the lime particles bond with each other and with sand. When the plaster dries, the calcium hydroxide reacts with atmospheric carbon dioxide to form insoluble calcium carbonate. Therefore, only lime-resistant pigments can be used for this technique, mainly inorganic pigments.

Fresco secco painting is performed on a finished, dried lime-plaster wall with pigments in an aqueous binding medium. The wall is impregnated with limewater, and the pigments are dispersed in water and a solution of casein. Secco painting must be applied in a thin layer, and the pigments must be resistant to lime.

The silicate technique eliminates the disadvantage of traditional fresco painting, that is, its sensitivity to atmospheric pollutants such as sulfuric acid. Potassium water glass is used as the binder. Only alkali-resistant pigments and water glass are used. Water glass reacts with the atmospheric carbon dioxide to give silica and calcium silicate, which form a water-permeable layer. The technique was discovered by KEIM in Munich, and “Keim's silicate paint” is still available today.

In the encaustic technique, the powdered pigments are mixed with beeswax and a small amount of dammar and melted to a pasty waxy paint. This is applied to canvas with special heated tools or to plaster-walls and results in a painting of high tinting strength and high fastness to humidity and air pollution.

7.7. Silk Paints

Paints Fixed by Ironing. Once the paint has dried, it is fixed to the silk with a hot iron at ca. 150 °C. The main advantage of these widely used iron-on paints is the simple method of fixing, which can be carried out at home, and the higher lightfastness of the pigments used in this type of silk paints. The disadvantages are limited flow behavior, poor solubility, and a somewhat stiffer texture of the silk afterwards.

Commercial iron-on paints consist mainly of aqueous pigment dispersions finished with dispersants and binders based on polyacrylics or polyurethane.

Dyes Fixed by Steam. After drying, these dyes are fixed in special steaming equipment. Those involved in silk screening as a hobby without access to such equipment can use a domestic steam pressure cooker as an alternative.

The main disadvantage associated with steaming lies in the method of fixing itself. The advantages of steam-fixed dyes are very good flow behavior, good solubility, high brilliance, good fastness, and the very soft texture of the painted silk. Silk dyes for steam fixing mainly consist of aqueous solutions of reactive or acid dye.

7.8. Paints for Graphic Techniques

Less common in the field of artistic techniques but nevertheless of importance are printed graphics.

Copperplate engraving is rarely used today, but wood- and linocut, etching, and lithography are still employed. For most of these applications the paint is based on oleic binders, and only for linocut is an aqueous paint used. Linoleum does not permit very delicate cutting, and it is characterized by blocky or posterlike forms. The technique has a certain popularity among artists and in schools for the production of more casual work. Many artists of the 1900s like Matisse, Picasso, Vlaminck and Rholfs preferred it to the more gnarled woodcut. Waterbased linocut paints are preferred for this application. The use of commercial printing inks is not recommended [13]. These waterbased paints are similar in composition to aquarelle and gouache paints, and certain properties are intermediate between the two, but the drying time of this type of paint is considerable longer than that of aquarelle or gouache. It contains organic and inorganic pigments, gum arabic, fillers, wetting agents, preservatives, glycerol, and nontoxic glycols. The characteristic effect of the colors is mainly semiopaque or semitransparent.

Lithography (⟶ Imaging Technology – Lithography (Planographic Printing, Offset)) requires various artists' materials: gum arabic, oil of turpentine, shellac, asphalt, rosin, talc, and others. Drawing materials are crayons, watercolor crayons, waxchalk, chalk, and India ink. India inks contain shellac (solved with borax in water), carbon black, and water. Others additionally contain beeswax, paraffin, or soap [35].

The printing ink was based on boiled linseed oil, linseed stand oil, and/or alkyd resins. Formerly artists produced the paint themselves from pigment and linseed oil. Today, offset printing oil is generally used.

7.9. Other Artists' Materials

Primers are used to seal porous surfaces before applying colors. Priming provides a smooth surface, which ensures that the subsequent paint layers adhere firmly. Primers are based on alkyd resins, acrylic emulsions, or linseed oil. They are pigmented with titanium dioxide or chalk. In oil painting, canvas, hardboard, bare wood, and other grounds are glue-sized before the primer is applied.

Solvents are used to dilute colors and clean up tools and materials. Solvents normally evaporate completely after application. The most widely used are white spirit, freshly distilled oil of turpentine, petroleum distillates, as well as brush cleaners and paint removers created as different mixtures by paint makers.

Mediums are used to improve the physical properties and behavior of a color. They are essential for certain techniques and are mixed in certain proportions with the paint. Mediums contain the same binder as the paint system or a compatible binder:

alkyd resins, dammar, acrylic resins or ketone resins for oil colors; acrylic emulsions for acrylic paints; gum arabic, starch, dextrin, and others for watercolors and gouaches. Some additionally contain thickening agents or other additives.

Varnishes provide a clear, transparent coat which gives substantial protection against environmental influence, but especially against dirt. The optical properties strongly influence the final appearance of a picture. Modern synthetic varnishes do not produce the same amount of gloss and color saturation as traditional varnishes. Molecular mass and refractive index are factors determining the optical properties of varnishes [36]. Changes in solubility, brittleness, crosslinking, and others result from unavoidable ageing. Resins for varnishes are mastic, dammar, acrylic, and ketone resins, and in some cases poly(vinyl acetate) and low molecular mass hydrocarbon resins. They are dissolved in white spirit, oil of turpentine, or ethanol.

Modern commercial varnishes contain UV-absorbing substances.

Retouching varnish can be applied after drying of oil paintings to give a temporary protection, but mainly for making a uniform surface between several layers of oil paint. After 10 or 12 months a normal picture or final varnish can be used to give the intended final protection. Beeswax or synthetic waxes and inorganic matting agents are added to varnishes for matte effects.

Fixatives are dilute solutions of acrylic and ketone resins in white spirit or of shellac in ethanol for fixation of drawings made with pencil, charcoal, chalk, pastel, and aquarell and gouache paintings.

Canvas is a flexible support woven from cotton, linen, or polyester yarn. The durability and stability of canvas depend on the type of yarn and the compactness and grain (texture) of the fabric. Normal canvas is already treated with an acrylic primer, but it can also be prepared in the traditional way with aqueous glue (size) followed by a stiff gesso which consists of chalk or light spar, linseed oil, and some aqueous glue.

Good quality watercolor *paper* is manufactured from cotton fibers, which impart strength and durability. It must be acid-free. Gelatin sizing gives a strong paper which is recommended for a wide range of water-based media (also gouache and acrylic).

Other types of papers of different weight and thickness, different sizing, grain, texture, as well as vellum and parchment, are available for gouache, acrylic, and oil techniques. Normally they should be prepared with gesso; oil paint in particular needs an isolating ground to avoid absorption of oil by the paper.

There is a wide range of artists' *brushes* for all painting techniques and materials, even for pastels. Most brushes are made from natural bristle, natural hair, or synthetic fibers intended to simulate the characteristics of the natural fibers. Aquarelle and wash brushes are maufactured from finest pure red sable, but ox, pony, and goat hair are also used. For oil, acrylic, or gouache painting the artist can use stroke brushes of different types of hair and a range of hog brushes.

Other accessories for artists are easels, palettes, palette knives, tiles, saucers, dippers, charcoal, rubbers, pencils, cutters, and tools for calligraphy, etching, lithography, and linocut.

1. Introduction

Asbestos (Greek: inextinguishable) is the common name of a number of naturally occurring, hydrated silicate minerals that possess a crystalline structure and low thermal conductivity. They are incombustible in air and separable into filaments. These minerals occur as extremely thin flexible fibers having great tensile strength and thermal stability, and they can be spun into yarn and made into textiles. There are some 3000 recorded uses of asbestos including "fireproof" textiles, paper and boards, clutch and brake linings, asbestos cement sheets and pipes, flooring and roofing products, electrical and thermal insulating materials, coatings, and heat shields.

Table 1. Classification of varieties of asbestos minerals

Group and Variety	Formula
Amphibole	
Anthophyllite	$Mg_7Si_8O_{22}(OH)_2$
Amosite	
(brown asbestos)	$(Fe^{2+}Mg)_7Si_8O_{22}(OH)_2$
Crocidolite	
(blue asbestos)	$Na_2Fe_2^{3+}(Fe^{2+}Mg)_3Si_8O_{22}(OH)_2$
Tremolite	$Ca_2Mg_5Si_8O_{22}(OH)_2$
Actinolite	$Ca_2(MgFe^{2+})_5Si_8O_{22}(OH)_2$
Serpentine	
Chrysotile	
(white asbestos)	$Mg_3[Si_2O_5](OH)_4$

The term asbestos was first used mineralogically in the middle of the 19th century with regard to a fibrous amphibole mineral discovered in the Italian Alps. The six major types of asbestos in use fall into two major groups: serpentine, having a layered silicate structure, and amphibole, having an SiO_4 chain structure. *Chrysotile* (white asbestos) is the sole member of the serpentine group. Chrysotile asbestos accounts for over 90 % of the world's asbestos production. Of the five members of the *amphibole group,* crocidolite (blue asbestos) and amosite (brown asbestos) are widely used commercially and tremolite and actinolite less so (Table 1).

Asbestos has been known and used in small amounts for thousands of years, but it was not widely used prior to the latter part of the 19th century [3]. Asbestos was first mined in the Quebec, Canada, chrysotile fields in 1878, followed by Russia in 1885 and South Africa in 1906.

Within 20 years of the first industrial production of asbestos, the public health hazards associated with asbestos started to come to light. Between 1890 and 1895, 16 out of 17 workers in a French asbestos weaving factory had died; by 1899, 11 men who had worked in an asbestos spinning factory in the United Kingdom had died at about the age of 30, having spent the whole of their working lives in this occupation (cording). The last of these deaths was reported to the Departmental Committee for Compensation for Industrial Diseases (U. K.) in 1906; this was the first recorded case of the disease that has become known as *asbestosis* [5]. The first complete description of asbestosis appeared in 1927 [6], [7]. Asbestosis and other asbestos-related diseases are treated in detail in Chapter 9.

10.1002/14356007.a03_151

The widespread commercial use of asbestos over the past 100 years has led to its uncontrolled distribution throughout much of the industrialized world and its appearance in the general environment. The concentration of asbestos fibers in the urban atmosphere is actually in the lower part of the range 10 – 100 ng/m^3, but this can rise substantially in certain locations [8–12]. For example, in the vicinity of factories using asbestos, concentrations of asbestos fibers in the external atmosphere up to 5000 ng/m^3 have been reported. In buildings where asbestos is being worked with or damaged, the concentration of asbestos in the air can be as high as 800 ng/m^3 [11], [13], [14]. Low concentrations of asbestos are also found in water, beverages, and pharmaceutical and other medical products [9], [11], [15–23].

All commercial asbestos minerals are hydrous silicates of either the serpentine or the amphibole group. The serpentine minerals, which include chrysotile, have relatively simple chemical formulas; e.g., for chrysotile it is $Mg_3[Si_2O_5](OH)_4$. (See Figs.1,2,3) Amphiboles have a widely varying nature and they are best considered by the general formula $A_{0-1}X_2Y_5Z_8O_{22}(OH, F)_2$; the substituents are: A = sodium or potassium; X = sodium or calcium; Y = magnesium, iron, or aluminum; Z = aluminum or silicon. It is not uncommon that small amounts of elements such as chromium, nickel, and titanium occur; usually many other elements are present in trace amounts. Minerals can have wide ranges of composition but still possess their characteristic structure and general formulas.

2. Crystal Structure

2.1. Serpentine Minerals

Chrysotile is a serpentine mineral, and these have layered silicate structures. The layers are made up of silicon atoms, each surrounded by four oxygen atoms at the corners of an almost regular tetrahedron. The magnesium atoms are also surrounded by six oxygen atoms, each at the corner of an almost regular octahedron. The SiO_4 tetrahedra, lying on their triangular bases and with the apices all pointing in the same direction, are linked by sharing all basal oxygen

Figure 4. Plan and elevation view of idealized structure of serpentine minerals
Reproduced by permission [1]

atoms to form a continuous layer. Gaps in the plane formed by apical oxygen atoms are filled by OH ions to form a regular and approximately close-packed array of (O, OH) at this level. Lying above this plane is an array of magnesium atoms and above these a plane of OH ions such that the magnesium atoms are surrounded by octahedra of (O, OH) ions. Each Mg has a triangle of 3 (OH) above it and a triangle below of 2 (O) and 1 (OH), rotated by 60 degrees with respect to the first. The structure is best understood by the plan and elevation view in Figure 4. The chemical content of a unit cell is $Mg_3Si_2O_5(OH)_4$.

In building up the serpentine structure, composite layers of the type described above are superimposed; the interlayer distance is approximately 0.75 nm. However, one layer may be placed directly above another or there may be displacement or rotation between layers. This leads to the possibility of different stacking frequencies, different symmetries, and multilayer unit cells. One-, two-, three-, six-, and nine-layer unit cells are known. The symmetry may be trigonal, hexagonal, or monoclinic. Disordered stacking can also occur.

The structure described above is that of lizardite. These minerals are mostly fine grained and have platy morphology but some have lath-like structures with elongation parallel to the *a* axis.

The asbestiform morphology of chrysotile is not the result of an obviously layered crystal structure. High-resolution electron micrography shows that in chrysotile the structured layers are curved about the direction of the *a* axis to form either scrolls or concentric circled tubes [24]. Each scroll is formed from a closely connected double layer having magnesium hydroxide units on its external face and silica units on its inner face. The details of a small section of the scroll

show the structure of the double layer and of the unit cell based on $Mg_3(Si_2O_5)(OH)_4$ (Fig. 5).

The diameters of the tubes are about 20 nm. A sliver of chrysotile asbestos with a cross section of 0.1 mm^2 contains about 2×10^7 tubular fibrils all in approximately parallel orientation. It is therefore possible to strip very fine threads from an asbestos fiber bundle, each of which contains many thousands of fibrils.

Figure 5. Schematic diagram of the structure of a chrysotile fiber formed of several scrolls of individual crystallites
a) Unit cell; b) Hydroxide ions; c) Magnesium ions; d) Magnesium hydroxide layer; e) Silica layer; f) Fiber axis Reproduced by permission [1]

The reason for the curving of the layers is the polar and composite structure of the fundamental sheet. The silicon component tends to have a smaller repeat dimension than the magnesium component, and the mismatch between the two can be overcome by bending, with the magnesium-containing octahedra on the outside of the curve.

The growth of very thin fibrils is more readily understood for chrysotile than for amphibole asbestos. When chrysotile tubes are formed, one radius of curvature may be the most stable, and this may impose an upper limit on the diameter of the tubes.

2.2. Amphibole Minerals

The fundamental unit of the amphibole structure is the chain of SiO_4 tetrahedra linked by corner oxygen atoms as shown in Figure 6. The characteristic chain formula is Si_4O_{11}, and the repeat distance along its length is about 0.53 nm. The chains are four tetrahedra wide and are very long. Fibrils of asbestiform amphiboles run parallel to the chain length.

In amphiboles the Si_4O_{11} chains are linked laterally by cations such as magnesium and calcium. In tremolite the magnesium ions link chains by strips of Mg(O,OH) octahedra. The calcium ions link neighboring chains, and they occur in distorted polyhedra of oxygen atoms.

Table 2. Physical properties of asbestos varieties

Property	Chrysotile	Anthophyllite	Amosite	Crocidolite	Tremolite	Actinolite
Tensile strength, kg/cm^2	31×10^3	24×10^3	25×10^3	35×10^3	$<5\times10^3$	$<5\times10^3$
Young's modulus, kg/cm^2	1.65×10^6	1.58×10^6	1.65×10^6	1.9×10^6	–	–
Flexibility	good	fair to brittle	fair	good	brittle	fair to brittle
Specific gravity	2.55	2.85 – 3.1	3.43	3.37	2.9 – 3.2	3.0 – 3.2
Hardness (Mohs)	2.5 – 4.0	5.5 – 6.0	5.5 – 6.0	4.0	5.5	6.0
Specific heat, kJ g^{-1} K^{-1}	1.13	0.89	0.81	0.84	0.89	0.91
Resistivity, MΩ cm	0.003 – 0.15	2.5 – 7.5	up to 500	0.2 – 0.5	–	–
Magnetic susceptibility (mean χ_g at $H = 7.98\times10^5$ A/m)	5.3×10^{-6}	14.3×10^{-6}	78.7×10^{-6}	60.9×10^{-6}	–	–

Table 3. General optical properties of asbestos varieties

Asbestos	Color	Pleochroism	Birefringence	Orientation	Extinction
Chrysotile	white	nil	moderate, 1st order	length slow	parallel
Anthophyllite	white	nil	moderate, low 2nd order	length slow	parallel
Amosite	ash grey	nil	strong, 2nd order	length slow	parallel
Crocidolite	dark blue	grey-blue to dark blue	weak (masked)	length fast	parallel
Tremolite	white	nil	moderate, low 2nd order	length slow	oblique (max. 20 degrees)
Actinolite	dark green	pale green to deep green	moderate, low 2nd order	length slow	parallel

Most amphiboles are monoclinic as a result of the way in which successive chain units are stacked with respect to each other. However, anthophyllite is orthorhombic and the relation of its unit cell to that of a monoclinic structure is shown in Figure 7.

The chainlike structure of amphiboles affords good cleavages along (110) planes. If the chains themselves and their linkage across Y sites are considered the strongest points of the structure, paths of weakness can be traced as in Figure 8, and the average path can be taken as defining a likely cleavage plane.

Figure 8. Schematic illustration of amphibole structure as seen along the z axis
Probable paths of weakness are shown, causing cleavages intersecting at approximately 57 degrees.Reproduced by permission [1]

The physical properties of asbestos do not result wholly from to the chainlike structure of amphiboles or their good cleavage. Many amphibole minerals are not asbestiform, although they possess chain structure and good cleavage.

3. Physical Properties

Some of the physical properties of the asbestos varieties are shown in Table 2.

Tensile Strength. One of the most important and most commonly quoted physical properties of asbestos fibers is tensile strength. Measurement is made on specimens 3 – 4 mm long (minimum), using for example the Marsh microtensile testing machine. Under the influence of heat, the tensile strength of the major types of asbestos fibers increases slightly before diminishing rapidly as structural changes and decomposition occurs (Fig. 9).

Surface Area. The most important parameter for industrial applications is surface area. Each process requires asbestos fibers with a critical degree of fiberization, which parallels surface area. For example, chrysotile fibers prepared for use in brake linings have a different degree of fiberization from those prepared for

making asbestos textiles. The required degree of fiberization is achieved by milling the raw asbestos; in multistage manufacturing processes account must be taken of any further fiberization that may occur.

Figure 9. Tensile strength changes in heated asbestos fibers
Reproduced by permission [1]

Ideally, a fiber of cross section area *a* will split into *n* fibers of average area of cross section *a/n* without breaking into shorter lengths. Under these circumstances, the degree of fiberization has increased *n*-fold.

Raw amphibole asbestos, i.e., asbestos shipped to refineries from mines, has an absolute surface area of $6-20\times10^3\,cm^2/g$, whereas for chrysotile, the value may be up to $30\times10^3\,cm^2/g$. The absolute surface area of typical asbestos fibers used in manufacturing processes is $30-90\times10^3\,cm^2/g$, which can be raised to $140\times10^3\,cm^2/g$ by gassing out at high temperature.

Specific Gravity. For the determination of specific gravity, prepared fiber blocks of approximately $1\,cm^3$ are outgassed under water for several hours and then weighed in water.

Electrical Data. The only available electrical parameter on asbestos is volume resistivity, which is low for chrysotile and very variable for amphibole fibers.

Magnetic Susceptibility. Generally magnetic susceptibility is low, but there are considerable differences between that of the high-iron amphiboles and anthophyllite and between the amphiboles and chrysotile.

Optical Properties. General optical properties and refractive indices are compiled in Tables 3, 4.

IR Spectroscopic Data. The use of IR spectroscopy in identification and structural studies of asbestos is relatively new. All types of asbestos exhibit strong absorptions around $1200-900\,cm^{-1}$ because of Si–O stretching vibrations and around $600-300\,cm^{-1}$ because of Si–O chain and ring vibrations. Additional peaks below $600\,cm^{-1}$ correspond to cation – oxygen vibrations. In theory, four cation sites for the amphiboles can be distinguished; however, in practice, it is difficult to detect more than two of these peaks. The O–H stretching vibrations are found in the region $3600-3700\,cm^{-1}$; their amplitude corresponds to the OH concentration of the sample.

The three major types of asbestos can readily be identified by peaks at $305\,cm^{-1}$ for chrysotile, $318-320\,cm^{-1}$ for crocidolite, and $330-332\,cm^{-1}$ for amosite. Principal absorption peaks for different types of asbestos are given in Table 5.

Table 5. Principal IR absorption peaks for asbestos minerals (wavenumber, cm^{-1}) Distinguishing strong (s) and week (w) peaks are indicated.

In environmental samples it is possible to detect 3 % of crocidolite in the presence of amosite. There is a difficulty when IR spectroscopy is used to assess airborne asbestos because a sample must be a minimum of 0.2 mg, which is a considerable weight by airborne sampling techniques.

The decomposition of asbestos by heat can also be followed by infrared spectroscopy as well as differential thermal analysis.

4. Chemical Properties

Thermal Decomposition (Table 6). All forms of asbestos break down progressively to simpler components (e.g., pyroxenes and silica) when heated to temperatures in the range 600 – 1000 °C (see also Fig. 10). Reactions of asbestos, as such, with other materials at high temperature therefore do not exist. In any reactions involving high-melting metals or fused salts, for example, sodium carbonate fusion, primary breakdown of the mineral is assumed to occur first, followed by reaction of the products with the fusing material. At lower temperature asbestos fibers resist attack by molten materials.

Asbestos fibers as such do not have a melting point; only the decomposition products melt. If the latter contain iron pyroxenes, fusion generally occurs between 1000 and 1100 °C, e.g., in the case of amosite and crocidolite. High-magnesium varieties, e.g., chrysotile and anthophyllite, decompose to give magnesium pyroxenes in the products, which melt at about 1450 °C.

Figure 10. Typical thermal analysis of chrysotile
A. DTA (differential thermal analysis) at 10 °C/minB. TGA (thermogravimetry analysis) at 2.5 °C/minReproduced by permission [1]

Reactions with Acid and Alkali. Strong acids rapidly decompose chrysotile with removal of all the MgO and H_2O content. However, amphibole fibers show various degrees of resistance to reaction with acids. All varieties of

asbestos resist prolonged attack by strong alkali, e.g., 5 M sodium hydroxide solution, at least up to 100 °C. Typical acid resistance curves for asbestos fibers refluxed in 4 M hydrochloric acid are shown in Figure 11.

Figure 11. Typical acid resistance curves for asbestos fibers refluxed in 4 M hydrochloric acid

Surface Characteristics. The outer surface of chrysotile fibers consists largely of $Mg(OH)_2$ and behaves as such. The equilibrated pH in carbon dioxide-free distilled water is 10.33. The surface charge in water is positive at a pH lower than 11.8 and rises to a maximum at a pH of 3. With high acidities the charge falls off rapidly as magnesium ions are removed and the silicous surface is exposed. This positive charge renders chrysotile attractive to most other materials in solution that carry a negative charge. However, the surface of amphiboles is like that of silica and carries a small negative charge in water.

Chrysotile has a large specific surface area; this, together with its molecular configuration, enables it to absorb gases fairly readily, particularly highly polar molecules, such as water. In a liquid, absorption can be complicated by competition between the solvent and the solute. The affinity of chrysotile for liquid organic compounds decreases in the following order: ethanol, butanol, benzene, naphthalene, anthracene, hexane. The absorptivity of amphiboles apparently has not been as well studied.

5. Occurrence and Extraction

The three main types of asbestos that have had wide commercial exploitation are chrysotile, amosite, and crocidolite. Of these, chrysotile is by far the most abundant and most widely used. Three others in decreasing order of importance are anthophyllite, tremolite, and actinolite. The last material, although not uncommon as a mineral, is rare in asbestiform habit. Chrysotile exists as yellowish or greenish-white fibers, usually silky in nature. Crocidolite is blue and less silky, and amosite has white, grey, pale yellow, or pale brown fibers that are more brittle than those of the former two varieties. Amosite is not strictly a mineral name, but a commercial name derived from the initial letters of Asbestos Mines of South Africa. Amosite usually consists mainly of the amphibole mineral grunerite, but appreciable amounts of other amphibole fibers are present in some specimens. All forms of asbestos are metamorphic minerals that are closely associated with their parent rocks.

Chrysotile veins form an irregular lattice work in the host rock from which the mineral is obtained by removal of the whole rock, crushing, and extraction at the refinery. Open-pit methods have proved the most economical way of working chrysotile deposits (e.g., in Quebec). Underground mining, particularly block caving, is practiced, e.g., in the Soviet Union, China, and southern Africa; the depth of the mines may exceed 300 m. The mining of amphibole asbestos is almost completely confined to South Africa.

In Canada, over 95 % of all asbestos ore is mined in open-pit operations involving drilling and blasting. The broken ore is loaded into trucks

(35 – 200 t capacity) and hauled to the primary crusher. Overburden and waste rock removed in development of open pits is similarly loaded and hauled to waste dumps. Primary crushing reduces the ore to a size of about 15 cm. After screening the average is reduced to a maximum size of approximately 7.5 cm, followed by wet-rock storage or drying. The ore, delivered by conveyor, is dried in vertical fluidized-bed dryers or in rotary dryers. Using a drying time of 1 – 15 min and an inlet air temperature of 430 – 1000 °C results in a moisture loss of 3 – 18 wt %. The outlet gas is maintained at 60 – 180 °C to prevent damage to bags in dust collection units. The dry ore is conveyed to a storage building. The residual heat in the ore is sufficient for complete drying.

Ore from storage is run over shaking screens equipped with aspirator hoods at the discharge end. The shaking action separates the freed fibers from the rock; they are lifted by air suction and removed from the airstream by a cyclone separator. The rock is further crushed and screened to remove more fiber and the process repeated. The asbestos fibers are freed from dust, rocks, and other material by passage over cleaning screens. After grading the fibers are bagged: either loosely packed in multiwall paper bags or pressure packed in 45-kg units in multiwall paper, plastic, or coated plastic fiber bags. Further storage and shipment is by palletized units of one or more tons.

Because fiber is extracted by a completely dry process, dust is generated in various phases of the operation, and this must be well controlled. Methods include wetting, high-efficiency cyclones in the bag houses, wet scrubbers, and electrostatic precipitators.

6. Uses and Asbestos Substitutes

Asbestos has become very widely used because it is a low-cost material with very desirable chemical and physical properties. This unique combination makes the economical replacement of asbestos very difficult in many applications. Heat and fire resistance, the most widely known property, is not as great as is popularly believed. Asbestos cannot be classified as a refractory, but its properties are sufficient to withstand superheated steam and other high-temperature industrial environments. Whereas major loss of strength can occur at temperatures in the range 300 – 500 °C, useful performance can be obtained at higher temperatures, in some cases up to 1700 °C.

Other properties contribute to the value of asbestos as an industrial material: its resistance to chemical and biological attack make it valuable in applications involving hostile environments and in achievement of a useful service life. The friction and wear characteristics of chrysotile and its thermal decomposition product forsterite (a nonfibrous silicate) make chrysotile a widely used material in such applications as friction (clutch and brake linings), and bearings; the high length to width ratio of asbestos fibers and their tensile strength make them useful as mechanical reinforcers in both polymer- and cement-based products.

Heat Protection. Fire and heat protection wear is made from asbestos cloth; an aluminized surface is bonded to it by thermosetting resins to give a heat-reflecting surface.

Substitutes. Heat-resistant nylon fibers, e.g., Nomex (Du Pont), can be used in place of asbestos. These fibers also protect against chemical hazards (not strong acids) and can be laundered with little deterioration in properties. Nomex is three times more expensive than asbestos but it has a much longer useful life. Special wool blends, e.g., Multitect (Multifabs Ltd., Derby), can protect against molten steel splashes at 1500 °C. The material is resistant to chemical attack, can be laundered with no deterioration in properties, is surprisingly resistant to ignition and flame spread, and is priced competitively with asbestos-based products.

Bleached tetrafluoroethylene fibers, e.g., Teflon (Du Pont), can be used to protect against flash fires and have been used to make suits for Apollo astronauts and for missile fuel handling.

Fire Blankets, Curtains, and Aprons. In general, the materials detailed above are suitable.

Substitutes. A sandwich of ceramic fibers between layers of glass cloth (Marglass Ltd.) is effective against flame and molten metal hazards.

Electric Insulation. Asbestos is widely used in the form of paper, tape, cloth, and board for

electric insulation. Frequently it is applied as a felted material and as a filler for natural and synthetic insulating resins. Loss of strength can develop at above 200 °C if prolonged heating in air is involved.

Substitutes. Glass fabrics of all types (cloth, tape, tubes, cord) are suitable but cannot be used where severe flexing is involved. Polyimide and polyethersulfone are examples of high-temperature-resistant, thermosetting materials used as wire and cable coatings where their ability to stand high temperature, plus toughness and flexibility, justify the cost. Ceramic fiber cloth tape or sleeving may be used with fiberglass inserts at temperatures up to 530 °C.

Filters. Asbestos cloth is used for bulk liquid filters, e.g., for beer.

Substitutes. Expanded perlite and vermiculite products can substitute asbestos as a filter material. Teflon fluorocarbon fibers withstand temperatures up to 300°C, coupled with a corrosive chemical environment.

Ropes, Yarns, Tapes. Asbestos in the form of rope, yarn, and tape is used for many purposes.

Substitutes. Glass may be used, but it softens at about 300 °C. For higher temperatures, continuous ceramic and silica fibers can be used as suitable replacements if price permits.

Thermal Insulation. Asbestos insulation board, asbestos spray, and lagging fall into this group of products.

Substitutes. Glass fiber, mineral wool, vermiculite, perlite, and aluminosilicate ceramic fiber are all suitable. For high-temperature insulation vermiculite is normally bonded with a high-alumina cement or fire clay (satisfactory up to 1100 °C). Expanded perlite is used as an insulating cover on the surface of molten metal, occasionally up to 1100 °C but best below 925 °C because of increase in thermal conductivity of expanded perlite above this temperature.

Packing Materials. Woven and nonwoven asbestos blankets are used as dry packings, e.g., in prefabricated buildings, as furnace and kiln door seals, and as high-temperature caulking material.

Jointings. Asbestos can be bonded with various elastomers, e.g., rubber, polychloroprene, that are resistant to specific oils and solvents.

Gaskets. A sandwich of asbestos with paper or millboard is used between copper sheets in cylinder head gaskets. The material withstands hot gases, hot oil, and hot water – antifreeze mixtures.

Linings. A mixture of powdered diatomaceous earth and asbestos withstands a maximum temperature of 870 °C.

Substitutes. Almost all conventional refractory materials (insulating firebrick or calcined diatomaceous earth) or ceramic fibers are suitable.

Packed or Sprayed Products. Asbestos has superior chemical stability in some situations, e.g., in hot reducing atmospheres and under hot, stressed conditions.

Substitutes. Synthetic ceramic fiber products are suitable. Thermal stability is generally superior to asbestos and chemical stability usually good. Cost is higher than for asbestos but service life is increased. Less maintenance is required and there is increased process efficiency because of higher operating temperatures. Mineral fiber is cheap and mineral wool products are usually cost competitive with similar asbestos products, but mechanical and insulation properties may be inferior.

Millboard. The ease of shaping, insulating properties, impregnability with bonding agents or cement, ability to be wet molded, and compressibility make asbestos millboard one of the most versatile materials used in industry.

Substitutes. Millboards made from aluminosilicate fibers can provide direct replacement at extra cost.

Concrete Products. Asbestos cement is widely used in building and in industry. For high-density, high-surface building materials, approximately 12 – 15 wt% of chrysotile asbestos is normally added to hydrated Portland cement; the end product is compressed into flat or corrugated sheets or molded into other shapes. Asbestos wood (named because of its workability, not its content) contains approximately

25 % chrysotile fiber in hydrated Portland cement. The term "sprayed asbestos" generally refers to gun-applied hydrated cement containing about 60 % asbestos fiber. In industry, the major use is asbestos cement pipes for the transport of corrosive fluids.

Substitutes. Glass fiber-reinforced cement is made by adding approximately 5 % of relatively expensive alkali-resistant glass fibers to hydrated cement and other fillers. The resulting composite can be extruded, molded, or sprayed. It is marketed as CemFIL (Pilkingtons). Glass-reinforced gypsum concrete, and polyester are also available.

Friction Materials. Asbestos-based brake and clutch linings and pads are in widespread use. Automobile brake linings are usually molded from a mixture of short chrysotile fibers, phenolic resin, and fillers. Brake pads are made in this way, or a woven asbestos cloth, reinforced with brass wire and impregnated with phenolic resin, can be used.

Substitutes. Sintered metal-ceramic and metallized bonded products are available, but their high-thermal conductivity can adversely affect the brake fluid. Delaminated vermiculites maintain their strength at high temperature and are compatible with phenolic resins. Silicon nitride was used for the brake pads in prototypes of the supersonic passenger aircraft Concord at a cost of about U. S. $ 7000 per ton. Carbon – carbon composites were used in the Concords production. Steel, glass, mineral wool, and aluminosilicates have been used in phenolic binders, but none is as good as asbestos for such items as disk brake pads.

Dry Rubber Bearings. Asbestos cloth or yarn impregnated with phenolic resin is used in plain rolling bearings that are able to function effectively without lubrication (although they can also be lubricated). They are used, for example, in automotive steering columns, brake and clutch pedal pushers, bearings for textile spin-ning, frame spindles, food slicer bearings, copy machine rollers, large railway and marine bearings, or lock gates. The maximum operating temperature is 175 °C.

Substitutes. Polyester-bonded textile laminates with molybdenum disulfide or graphite and cellulose fabric-bonded phenolic laminates and polytetrafluoroethylene (PTFE) or graphite can be used up to 100 – 130 °C.

Composites. A thermosetting and sometimes a thermoplastic matrix (phenolic, silicone, or polyester) is reinforced by the addition of asbestos fibers and also sometimes by the addition of glass fibers, enhancing strength, stiffness, and toughness. The material is used in small machine parts, usually made by injection rolling.

Substitutes. Generally, glass fibers provide an adequate replacement for asbestos. Carbon fibers are used in special applications; they save weight but are expensive.

Miscellaneous. Asbestos felt impregnated with bitumen is used for roofing and damp courses. Floor tiles and high-temperature mastics (flexible fillers) may contain asbestos.

Substitutes. Conventional cellulose fiber papers and felts can be used in impregnated form. Glass fiber can replace asbestos for many applications. Mastics based on aluminosilicate fibers in colloidal silicate binder are used for refractory caulking.

7. Economic Aspects

The use of asbestos grew slowly during the early part of the 20th century and by 1930 a cumulative world total of approximately 5×10^9 kg of asbestos had been mined. Since the decade 1930 to 1940 production has accelerated such that the production for 1976 alone (ca. 5.6×10^9) exceeded the 1930 cumulative total. The U. S. Bureau of Mines has estimated that the world has a reserve base of 104×10^6 t of asbestos ore, 200×10^6 t of identified resources, and 15×10^6 t classified as hypothetical resources [4]. The world production of asbestos by principal producing countries is shown in Table 7.

8. Asbestos in the Environment and Waste Disposal

The amount of asbestos used in everyday appliances has been reduced. For example, asbestos blankets have been replaced by fiberglass ones and asbestos paper is no longer used in schools.

Table 7. World production of asbestos by principal producing countries

Year	Canada		South Africa		USSR		World total
	1000 t	%	1000 t	%	1000 t	%	1000 t
1948	590	63	38	4	–	–	–
1953	827	58	86	6	272	19	1420
1958	839	45	159	9	499	27	2055
1963	1157	46	187	8	685	27	2505

1979	1493	30	249	5	2100	42	4992
1980	1323	27	277	6	2250	45	4988
1981	1133	24	273	6	2340	49	4817

However, the general population, without its knowledge, is still exposed to asbestos. One of the most likely ways this may occur is through drinking water [25]. Asbestos can enter the water supply in many ways. Erosion from industrial deposits of serpentine minerals or improper disposal of asbestos washings can be sources of asbestos. Also, some water pipes are made of asbestos cement; erosion of these pipes can also provide a source of asbestos [26]. Many gaskets used in the water system are made from asbestos.

The amount of asbestos in water is difficult to monitor. The fiber concentration has been found to vary from 0 to 130×10^6 fibers/L (visible by electron microscopy).

In the United States some people presumably consume at least 2×10^9 fibers or 710 µg of asbestos per year through their drinking water. The effects of these levels on health is not known. Asbestos has also been detected in wine.

According to the voluntary labelling scheme devised by the Asbestos Research Council and the Asbestos Information Committee (UK) products containing asbestos should be marked as such and precautions against inhaling the dust should be on the package. However, this is not done.

Asbestos is contained in many do-it-yourself products, for example, many plugging materials, asbestos cement sheets, acoustic tiles, and insulating board. Sawing and cutting of these sheets and tiles invariably releases dust into the atmosphere. The level of asbestos dust produced during these activities is many times that of the safety standard; also, unlike in professional practice, there is no damping of the dust to reduce levels.

It is not known how long an exposure is necessary to cause mesothelioma. The least time recorded by Department of Health and Social Security statistics is three weeks. Seventeen cases were recorded in 1967 – 1968 in which no one had worked with asbestos. One man with mesothelioma had been exposed for only one day while sawing asbestos sheets.

Do-it-yourself products probably do not contain crocidolite, but other types of asbestos are thought also to cause mesothelioma. In the United States four cases of meso-thelioma were found among the families of 1600 workers handling amosite. In the United Kingdom there are four cases known caused by chrysotile.

Asbestos is used in brake linings and clutches; there is an elevated level of airborne asbestos around braking vehicles. People who repair brakes and clutches may inhale large amounts of asbestos. Car brakes need to have the asbestos dust blown out of the drums regularly. According to various reports this dust consists of asbestos not in its normal state, but decomposed by the high temperature caused by friction on braking. However, there have been cases recorded of people with mesothelioma exposed in this way, namely a young boy in the United States who used to help his father clean out brake drums and who died from cancer at a young age.

Some roads and footpaths are surfaced with asbestos-bearing gravel, and this may produce airborne asbestos. Also, humidifiers may contain water with high levels of asbestos. There are asbestos-bearing paints and cigarettes with asbestos filters (reportedly no longer used in U. S. cigarettes). Even powdered papier-mâché

mixes, which are widely used in schools, have been found to contain asbestos.

However, most people are not engaged in the installation of asbestos products or other activities involving high asbestos levels. Ambient air therefore constitutes the greatest source of atmospheric exposure for the population at large.

Atmospheric Concentration. Atmospheric asbestos concentration data are scarce, because of the cost and the difficulty in obtaining it. The average reported concentration of asbestos in urban air in the United States varies between 0.09 and 70 ng/m^3 and between 0 and 2400 fibers per cubic meter. Using concentration data expressed in terms of mass (representing 203×10^6 people) the percentage of the urban population at risk to various atmospheric levels of asbestos in the United States has been calculated and is shown in Table 8. Assuming that humans breathe 15 m^3 of air daily the annual amounts of inhaled asbestos can be estimated from the ambient atmosphere for the United States urban population: 50 % of the urban population inhales 110 µg or more of asbestos per year, and 10.5 % inhales 230 µg or more, compared with the range 0.05 – 0.5 µg for rural populations. People who live or work in or near asbestos mines and factories are exposed to even higher levels of asbestos.

Disposal of Asbestos Waste. Asbestos is a rock mineral and not acutely toxic. There is no reason why it should not be disposed of by landfill. However, there must be safeguards, particularly to prevent dust formation. The asbestos must be buried at a sufficient depth to prevent the surface from drying out. This presently is practiced in many countries. Wet waste may be disposed of as a slurry at a dry waste site providing quantities are not excessive.

The asbestos waste is placed in a sealed impermeable bag or other sealed receptacle, marked "Asbestos Waste" or particularly "Blue Asbestos, Do Not Inhale Dust." The major principle of disposal is that no dust be emitted into the air during transport or dumping. In order to avoid the risk of the receptacles breaking, vehicles used for transporting the waste should have a low discharge point in relation to the ground. Ideally, the waste is deposited at the foot of the waste site, thus minimizing the need for further disturbance as the site is formed; finally, the waste is covered with at least 22 cm of consolidated earth or other suitable material. Covering should be done immediately in the case of waste derived from blue asbestos; no waste should be left uncovered at the end of a working day.

National or local regulations governing the disposal of asbestos waste usually exist. For example, in the United Kingdom notification of removal or deposit of asbestos waste is covered by Section 3 of the Deposit of Poisonous Waste Act 1972 and there is parallel legislation in other countries.

9. Toxicology and Occupational Health

9.1. Asbestos-Related Diseases

The mining and use of asbestos have always been associated with disease among the workers involved. However, because prior to 1900 the number of people involved was not large, there was little to draw attention to these hazards. It is now well established that asbestos fibers can produce a number of medical effects, the most common of which are pleural thickening, asbestosis, mesothelioma, and cancer. These asbestos-related diseases can appear from several years to tens of years after the first exposure to airborne asbestos dust; the former increasing incidence of cases in many countries could be regarded as a result of past dust exposure, which was obviously too high.

9.1.1. Inhalation of Asbestos Dust

When dust-laden air is inhaled, most large asbestos fibers (10 nm or larger in diameter) are trapped in the mucous membranes and hairs of the nasal passages. Fibers of smaller size may enter the bronchial tree and are mostly cleared by the cilia lining the respiratory tract, particularly if they are larger than 5 nm in diameter. Smaller fibers, particularly if less than 3 nm in diameter, may enter the terminal bronchioles and alveoli. These smaller fibers, especially those with a diameter of less than 1 nm, are considered to be the most significant in inducing biological effects in humans.

Table 8. Inhalation of asbestos from ambient air

Proportion of urban	Atmospheric concentration		Annual inhalation	
population consuming indicated level or more, %	Fibers∗/m^3	ng/m^3	Millions of fibers∗	µg
50	5000	20	27.4	110
25	7500	28	41.1	158
10	10500	40	57.5	220
5	12500	48	68.4	268
1	16000	64	87.6	350
Rural population	–	0.01 – 0.1	–	0.05 – 0.5

∗ Fibers visible in the electron microscope, assuming 250 fibers per nanogram of asbestos

Some of the needle sharp fibers may penetrate bronchiolar and alveolar walls to remain in the interstitial tissue, or they migrate to the pleural surface or enter the lymphatic vessels. A high proportion of asbestos fibers that are retained in the lung become coated with a ferroprotein complex and become asbestos bodies. These asbestos bodies remain dormant in the lungs for many years, often presenting giant multinucleoate cells. After this time, the ferroprotein coat can break down, releasing pieces of fiber; this causes the lung tissue to be destroyed and to be replaced with scar tissue. In some cases its changes are particularly marked in the pleura, which becomes thickened. This is the start of asbestosis.

9.1.2. Pleural Thickening

Pleural thickening has been observed in some asbestos workers and also in some people living near asbestos dumps. It is a thickening of the surface of the lungs that occurs after exposure to asbestos dust. In the absence of asbestosis, pleural thickening itself does not have any ill effects; it is not necessarily associated with lung cancer or mesothelioma.

9.1.3. Asbestosis

Asbestosis is a fibrosis of the lungs caused by inhalation of asbestos dust and is commonly found in asbestos workers. It is a nonmalignant, progressive, irreversible lung disease characterized by diffuse intestinal fibrosis [27]. The disease develops slowly and is detectable by a combination of clinical, radiographic, and lung function tests. In the early stage there is uncertainty about diagnosis, and the characteristic symptoms are progressive breathlessness and an unproductive cough. The fibrosis tends to increase despite the removal of the patient from further dust exposure. The risk of developing asbestosis apparently is related to the duration and level of asbestos dust exposure. Detectable early stages at which removal from further dust exposure markedly influences the course of the disease have not yet been found. Cases of asbestosis have occurred in people many years after their last known exposure to the dust.

9.1.4. Cancer

Cancer of the larynx, stomach, colon, and rectum may be associated with asbestos. There is also an increase in the incidence of bronchial tube cancer or lung cancer in people who have had asbestosis. It is not yet certain whether asbestos can contribute to cancer when asbestosis is not already present. Over half the British death certificates recording asbestosis also record a lung cancer.

The first reports of a relationship between asbestos dust exposure and *bronchial carcinoma* were made in 1935 [28], [29]; this was confirmed by subsequent studies [30]. All commercially used types of asbestos have been shown to cause an increase in the occurrence of bronchogenic carcinoma.

There is no difference in the clinical behavior of carcinomas in asbestos workers as compared with nonasbestos workers. Most bronchial carcinomas arise in the epithelium of the major bronchi. Asbestos is also reported to cause alimentary tract carcinomas (esophagus, stomach,

colon, and rectum) among asbestos workers. No firm data are available to link asbestos exposure to other neoplasms. Suggestions that carcinoma of the ovary might be asbestos related have not been proved.

Lung Cancer and Cigarette Smoking. In 1968, important new information on the relationship between asbestos exposure and cigarette smoking was published [31]. This showed that the risk of developing cancer for asbestos workers who smoked was 90 times greater than for nonsmoking asbestos workers (Table 9). For this reason health education and antismoking campaigns are of particular importance in the asbestos industry.

Cancers of the Alimentary Tract. Cancers of the alimentary tract occur about twice as regularly among heavily exposed asbestos workers as among the general population. All types of smoking, the consumption of alcoholic beverages, and the chewing of tobacco increase the risk of cancer of the oropharynx and the esophagus [32]. The consumption of beer has also been correlated with mortality from rectal cancer. Persons having close relatives with a cancer of the alimentary tract are also at an increased risk. However, refusing someone employment as an asbestos worker can only be justified when all these factors are present. Larynx carcinoma has also been related to asbestos exposure and alcohol consumption [32].

9.1.5. Mesothelioma

Mesothelioma is a malignant tumor, exceptionally rare in the general population; however, it occurs most often between the 5th and 8th decade of life among asbestos workers [33]. It affects the lining of the thoracic (pleural) or, more rarely, abdominal cavity (peritoneum). Mesothelioma is usually associated with exposure to blue asbestos but has also occurred among workers exposed to other types of asbestos. The duration of exposure required to cause mesothelioma may be brief and the disease can appear at some considerable time later. Most cases of mesothelioma are related to past exposure to asbestos; present evidence indicates that insulation workers as a group are at highest risk. Few cases of mesothelioma have been reported in which no exposure to asbestos can be traced.

Diffuse malignant mesothelioma is a rapidly progressing disease and there are no reliable estimates for a five-year survival rate. In 70 – 90 % of the cases, patients have shoulder or chest pain as a primary symptom. The pain becomes sharper as the tumor invades the chest wall. However, the pain is not aggravated by breathing or chest wall movement. Eventually, the pain is severe enough to interfere with sleep and to require narcotic medication. Weight loss, weakness, and fever are less frequent but become more common as the tumor progresses. Fluid may build up in the lungs and is sometimes bloody – this must be removed by aspiration.

Detection and identification of mesothelioma during life is difficult. Life expectancy of a person with pleural mesothelioma averages about one year with occasionally patients living several years.

In addition, peritoneal mesothelioma may occur; the earlier symptoms of this are vague abdominal discomfort, loss of appetite, and constipation. Intestinal obstruction may occur later but it may be the presenting complaint if the patient delays seeking medical attention. Physical examination is unrevealing in the early stages. As time goes by the presence of an abdominal mass becomes apparent but even at surgery diagnosis is elusive. The disease progresses more rapidly than pleural mesothelioma and death as a result of intestinal obstruction is common. No effective therapy is available, any treatment is supportive.

9.2. Occupational Health

Official exposure limits to asbestos dust levels have been established in many countries. The exposure limits tend to vary from one country to another: the TLV (threshold limit value, United States) is 0.2 fibers/cm^3 (crocidolite, $>5\,\mu$m diameter), 0.5 fibers/cm^3 (amosite, $>5\,\mu$m diameter), and 2 fibers/cm^3 (chrysotile and other forms, $>5\,\mu$m diameter); the CL (control limit, United Kingdom) is 1 fiber/cm^3 (chrysotile). No MAK (Maximale Arbeitsplatz Konzentration, Federal Republic of Germany) has been established; all asbestos forms are classified as

Table 9. Mortality of asbestos workers by smoking habit

Smoking habits	Number of men	Observed deaths	Expected deaths
Never smoked regularly	40	0	0.05
History of pipe or cigar smoking only	39	0	0.13
History of regular cigarette smoking	283	24	3.16

A1 (human carcinogens), the lowest technically feasible level (TRK) being at 1 fiber/cm^3.

The standard method for measuring asbestos dust is the membrane filter method. The air is sampled in the operator's breathing zone and a known volume is drawn through a membrane filter. The filter is then made transparent and the number of fibers deposited on the filter fitting a standard definition of size and shape are counted using a phase-contrast microscope.

Control of Asbestos in the Workplace. Exhaust extract ventilation equipment and protective clothing must be provided. Respirators must be approved by the appropriate authority and provide protection against the asbestos level encountered by the worker.

The masks providing the best protection are usually battery-powered, positive-pressure types. Overalls provided are usually of the one-piece boiler suit type with close-fitting neck, wrists, and ankles. The overalls are usually of a finely woven synthetic fiber, to which the asbestos dust does not adhere very readily. Ideally, the feet should be protected by Wellington boots worn with the overall trousers outside the boots. The boots should not be worn outside the work zone. Fingernails are a notorious trap for contaminants; for this reason gloves should be worn.

The machinery and the work areas themselves should be kept as clean and free from dust as possible. Measures should be taken to create as little dust as possible during the work process, e.g., by damping materials or by complete closure of the work area. If this is impracticable, a dust-control system is required.

Asbestos should be transported around the workplace in closed receptacles, and these receptacles should be treated as asbestos waste after use and placed in other closed receptacles for disposal. Whenever specially designed premises and equipment are used for asbestos work, it is relatively easy, although expensive, to maintain safe conditions. However, most of the danger lies in demolition or removal work, and here, too, the respirators and overalls previously described must be provided and used. Whenever crocidolite is present or expected to be present high-efficiency respirators must be used.

Workers Precautions

1) Cigarette smoking greatly increases the risk of lung cancer. Cessation should reduce the number of deaths in asbestos workers.
2) The history of lung cancer in a first-degree relative (parents, siblings, offspring) has been shown to confer the same amount of risk as cigarette smoking; both factors are synergistic. Perhaps these persons should be removed from asbestos exposure.
3) Prior occupational exposure to carcinogens affecting the lung may also increase the risk of lung cancer in an asbestos worker. Such carcinogens include arsenic, chloromethyl ethers, chromates, coal tar, petroleum and petroleum products, creosote, mustard gas, nickel, radium, and uranium.
4) Nonmalignant respiratory disease may increase the risk of lung cancer, e.g., pulmonary fibrosis or chronic bronchitis.

According to a Norwegian study (1975), vitamin A intake at all levels of cigarette smoking may decrease the risk of lung cancer. High doses of vitamin A and its synthetic analogues (retenoids) have been shown to prevent lung cancer in laboratory animals. Asbestos workers should make sure of taking their daily requirement of vitamin A.

1. Introduction

In the United States the terms asphalt and bitumen are synonymous. However, their usage often varies in other countries. The American Society for Testing and Materials (ASTM) defines bitumen as a generic class of amorphous, dark colored, cementitious substances, natural or manufactured, composed principally of high molecular mass hydrocarbons, soluble in carbon disulfide [11]. Asphalt also is defined as a cementitious material in which the predominating constituents are bitumens. The terms bituminous and asphaltic then refer to materials that contain or are treated with bitumen or asphalt.

European and Eastern countries prefer to use the term bitumen, whereas in the Americas asphalt is more commonly used, with the terms considered to be synonymous under the above definitions. In the Federal Republic of Germany terms and definitions relating to bitumen and bituminous preparations are compiled in DIN 55946. The Europeans also call bitumen – aggregate mixtures, as used in road paving, asphalt, which is not consistent with the ASTM definition. Thus some confusion exists, which cannot be resolved by this treatise, other than by adhering as closely as possible to overall usage and practice. In this article the term bitumen is used preferentially, although at times it may be used interchangeably with asphalt when citing certain published literature.

The primary source of bitumen or asphalt originates in or is derived from petroleum crude oil, commonly referred to as petroleum or crude. It occurs naturally in rock strata of certain geological formations, from which it is produced by drilling, then recovered by natural flow or by pumping. Subsequently it is submitted to refinery distillation which yields a residual fraction containing bitumen. In certain areas of the world petroleum crude oil has escaped through the earth's surface layers, then aged and weathered for long time periods. This results in a natural or native deposit of bitumen, generally mixed with mineral matter. Common usage dictates the term *native asphalt* in this case (Chap. 2).

This article provides a brief overview of the more important technical aspects of petroleum-derived bitumen. An enormous amount of research has been devoted to this subject. The references listed herewith only touch the fringes of the subject.

Table 1. Three classes of native asphalt with typical properties and examples

Class	Nearly pure bitumen	Appreciable mineral matter	Small fraction of bitumen
Class name	asphaltite	lake asphalt	rock asphalt
Solubility in CS_2, %	98	53	7
Softening point, °C	195	93	–
Penetration at 25 °C	2	1	–
Specific gravity	1.07	1.40	2.30
Mineral matter	silica – carbonate	clay – silica	sandstone – limestone
Examples	Gilsonite, United States Bermudez, Venezuela	Trinidad, West Indies	Kentucky, United States Seyssel, France

2. Native Asphalt

The term native asphalt refers to a wide variety of materials found in nature and containing varying amounts of bitumen as defined by solubility in carbon disulfide. Native asphalt varies considerably in composition and properties. From a practical viewpoint, it is convenient to classify these asphalts into three groups according to their bitumen content, see Table 1.

There are many deposits of native asphalt occurring in various countries, the majority of which have little significant commercial usage. Some of the more commonly known sources are as follows.

Gilsonite. Native asphalt was discovered in Utah, United States, in 1882 and later developed commercially by S. H. Gilson, after whom it was named. This material, which varies somewhat from one vein to another, is characterized by its high softening point and low mineral matter content. For many years Gilsonite was extracted from mines by hand, whereas now it is recovered by means of high-pressure water jets. Its most common use has been in paints, primers, sealers, and floor tiles. More recently it has been coked in pilot tests to yield gaseous and liquid fuels.

Trinidad Asphalt. Trinidad Lake is situated on the island of Trinidad, West Indies. It covers a surface area of about 400000 m^2 and is about 90 m deep at its center; it has the form of an inverted cone. It was reportedly discovered in 1595 by Sir Walter Rayleigh and is estimated to contain about 6×10^6 t of asphalt, or pitch as it is often referred to.

The genesis of the lake was Cretaceous petroleum oil escaping in the Nariva time, forming a submarine seep on the sea bottom over a large uplift. The heavy oil and gas seeped through fissures and mixed with sediments, forming ultimately a lenselike body of asphalt heavy enough to remain at the sea bottom. During the unfolding and faulting, the asphalt rose some 1300 m through unconsolidated sediments to an exposed anticline.

The lake has been mined for many years by digging with mechanical machinery, transporting to stills where it is heated and screened, then run into wood or light steel drums. This material is known as refined Trinidad asphalt under the trade name Epuré and has been exported to many parts of the world. Epuré has found considerable use in European countries, where it is fluxed in minor proportions with petroleum asphalt cements. It is claimed by many to add service life when used in road surface mixes [12], [13].

Rock Asphalt and Oil Sands. Kentucky rock asphalt is found in deposits or beds 2 – 15 m thick in horizontal strata below an overburden of clay soil. It contains between 5 and 20 % bitumen and is recovered by simple quarrying, broken into lumps, and then crushed to a coarse powder. This product is then blended with a petroleum bitumen in order to upgrade the bitumen for use as a road mixture.

Athabaska sands from Alberta, Canada, are of special interest because of their reported reserve of over 300×10^9 barrels of oil. Currently the oil is being recovered on a sizeable scale by steam and kerosene extraction yielding a synthetic crude oil, termed syncrude (→ Tar Sands) [14]. The recovered oil is then processed using typical petroleum refinery methods. The oil sands can be classified as native bitumen or asphalt (small bitumen concentration). However,

the recovered syncrude is not suitable for manufacturing the normal bituminous products described in the following sections of this article.

3. Testing

The properties of bitumen are described by physical tests. Usually, consistency or some combination of consistency with other basic properties is measured. Testing and the control of properties through specifications are important in any discourse on bitumen. Only the most commonly used standardized tests are covered in this chapter; for more details, see the appropriate ASTM and DIN publications.

Softening point is a measure of the temperature at which a steel ball (9.5 mm diameter) passes through a disk of the sample and falls a distance of 25.4 mm (1 inch) when the specimen, ball, and bath of water or glycerol are heated at a specific rate (Fig. 1). Bitumen does not have a definite melting point but changes gradually from a solid to a fluid during an increase in temperature. The softening point as measured by this method approximates the temperature at which this takes place.

Figure 1. Softening point test (ring and ball)

Penetration involves the determination of the extent to which a standard needle penetrates a properly prepared sample of bitumen under specified conditions of temperature, load, and time (Fig. 2). The unit of penetration is 0.1 mm, which is generally omitted in favor of reporting just the measured number. The test range is from 0 to about 300. The harder materials are indicated by the lower numbers.

Figure 2. Penetration test (100 g/5s)

Viscosity is a measure of resistance to flow, that is, the internal friction of the bitumen. It is measured as the ratio of shear stress to shear rate and may be reported in different units depending on the apparatus used. Figure 3 illustrates the use of the vacuum capillary method (usually at 60 °C). On less viscous materials or at higher temperatures, viscosities are also determined using the Zeitfuch crossarm viscosimeter (capillary viscosimeter) [15]. Whereas the above test methods are routine, viscosity may also be determined at ambient or lower temperatures using more sophisticated instrumentation [16], [17]. In general,viscosity is perhaps the most important singular test quantity determined on any bitumen, mainly because it relates closely to both application and service conditions.

Figure 3. Vacuum capillary method for viscosity measurement (Cannon-Manning tube)
a) Timing marks; b) Filling line

A system for grading asphalt cement by viscosity was developed [18], [19]. It is based upon viscosity measurement at 60 °C. For example, an AC-20 grade is controlled to a viscosity of 200 Pa·s (± 20 %). Grades are then specified from AC-2.5 to AC-40. This system is almost universally used in the United States and is considered to be an improvement over the penetration grading system used in most other countries.

Flash point is defined as the lowest temperature at which a combustible or flammable material evolves sufficient vapor, under the conditions of the test, to form a flammable vapor – air mixture that flashes when ignited. On bitumen this is conveniently determined using the Cleveland open-cup method (ASTM 92–72, DIN 51376). Flash point measurements or values are related to the temperature at which the bitumen vapor may ignite under appropriate conditions. Flash test results, however, should not be interpreted as an indicator of safety control during storage or handling.

Ductility of a bituminous material is a measure of the distance in centimeters that it elongates before breaking when the two ends of a briquet specimen are pulled apart at a specified rate and temperature (Fig. 4). Ductility is a significant characteristic of bitumen but the presence or absence of ductility is more significant than the degree or the amount determined. Ductility does not measure any specific property but rather a combination of flow properties. It may be used in qualifying bitumen used in paving mixtures because it permits the mix to be slightly overstressed without cracking (see also [20]).

Figure 4. Ductility test

Fraass break point is a test applied to determine the temperature at which a layer of bitumen (0.5 mm) cracks or breaks under specified conditions of bending (Fig. 5). In principle it is a flexure test conceived to relate to ductility, but it is more adaptable to low-temperature testing. The reproducibility of the test is not good, but it has some relative value in judging low-temperature qualities.

Figure 5. Break point (Fraass)

The *thin-film oven test* is used to measure the relative viscosity increase or penetration hardening of a bitumen exposed to 163 °C in a 3.2-mm film. The bitumen film is exposed in a pan on an oven shelf for a period of 5 h. The ratio of viscosity at 60 °C after the test to before the test is a measure of consistency change related to changes found when processing bitumen through the hot-mix cycle. Ductility minimum is also specified on the thin-film test residue, serving as a more critical requirement than when applied to the bitumen before the test. The *rolling thin-film oven test* and the *rotating flask test* are modifications of the above involving a rotating movement of the bitumen film during exposure [21]. They are considered to be equivalent in both test values and test significance.

Other tests are often specified but are not illustrated here. For example, solubility in trichloroethylene is usually required to be at least 99 % in order to insure purity. The Oliensis spot test [22] is universally required on bitumen used in the United States for state and federal highways. This would outlaw products that have been overheated during manufacture or handling, thus upsetting their compositional balance.

Figure 6. Composition of various petroleum crude oils (concentrations in vol %)

4. Bitumen Production from Crude Oil

The largest source of bitumen is crude petroleum oil [23]. Of the approximate 1500 crude oil fields and pipeline streams in the Western World, only about one fourth are suitable for the manufacture of bituminous products. The rest are normally used for the manufacture of fuel products or chemical specialities.

Figure 6 demonstrates the reason that some crudes are more suitable for bitumen manufacture than others [24]. Typically the lower API gravity crudes have the highest bitumen content and the lowest percentage of distillable fractions, that is, gasoline, kerosine, and gas oils. The high-gravity crudes typically contain less bitumen and higher percentages of distillable fractions. The low-gravity crudes (low API degree) are called heavy crudes, or sour crudes if their sulfur content is high.

4.1. Distillation

Distillation is a necessary first step in the separation of a bitumen-containing residuum from crude petroleum. This process is referred to as straight reduction and is illustrated in Figure 7. Distillation separates the more volatile fractions, generally requiring first an atmospheric fractionator and then a second vacuum stage in order to remove the distillable fractions from the bitumen-containing residuum. All of this is accomplished in a continuous process. The temperatures shown in Figure 7 approximate the boiling ranges of the fractions being separated. A final cut-point temperature of 450 °C is necessary to separate the bitumen-containing residuum from the crude oil. The temperatures reported are atmospheric equivalent vapor temperatures (AEVT), because reduced pressure is used at this point. The actual temperature needed is dependent upon the pressure and the nature or makeup of the crude oil being processed. As indicated by the heavy line in Figure 7 the most direct means of manufacturing is by straight reduction to bitumen of grade AC-2.5 to AC-40.

4.2. Solvent Separation Methods

Solvent treatment is often applied to a vacuum residuum in order to recover additional quantities of gas oil and lube distillates (deasphalted oil) and obtaining a bitumen fraction (precipitated asphalt) at the same time. This process is known as *solvent deasphalting* (SDA) and is commonly carried out using propane and/or butane as the solvent [25]. The *Residuum Oil Su-*

percritical Extraction (ROSE) process has been used to provide oil and bituminous fractions of different characteristics [26], [27]. In this process, illustrated in Figure 8, the residuum is contacted or mixed with the solvent at elevated temperature and pressure, then separated into an asphaltene concentrate and solvent. The extract fraction is then submitted to a second separator at higher temperature and pressure for separation of a resin fraction. In a similar manner the oil fraction is next separated. Both the SDA and ROSE processes provide bituminous fractions that can be used in the manufacture of bituminous products.

4.3. Continuous Air Blowing

The continuous air-blowing process is used in the manufacture of paving grades only when the available residuum feed must be increased in viscosityor when improved temperature susceptibility is required. As illustrated in Figure 9, this process involves the continuous processing of a vacuum residue (base stock or flux) through an oxidation tower held within the range of 230 – 270 °C while air is passed through the hot flux. This causes conversion within the flux, resulting in higher softening point, higher viscosity, and lower penetration. This process is occasionally used in European and Eastern countries for preparing cement grades, but it is seldom used in the Americas for that purpose.

4.4. Manufacturing Routes for Cement Grades

Bituminous cements may be prepared by any one of several routes depending on the crude being used and the processing applied [28]. If the crude feed permits, straight reduction to the desired grade is the most direct and most commonly practiced method. Blending or mixing of crude feeds is often practiced. If two or more crudes are processed separately with one yielding a low-viscosity residuum and the other a high-viscosity residuum, the products can be blended. If only a low-viscosity residuum is made, it can be blended with precipitated bitumen or it can be air-blown. If only a high-viscosity residuum is made, its viscosity can be regulated during distillation or it can be blended back to lower viscosity with gas oils or higher-

boiling fractions. Thus the refiner has several choices depending on his crude feed composition and the process facilities available.

4.5. Road Bitumen Compositions

In order to provide bituminous products of suitable handling and application characteristics, a great variety of types and viscosity grades are used. Some examples are compiled in Figure 10, which first shows the proportional amounts of gas oils (GO) needed or removed by distillation in order to meet the various viscosity grades of asphalt cement, i.e., AC-2.5 to AC-40 [29], [30].

The various cutback grades [31] are made by blending bitumen of specific penetration with naphtha, kerosine, and light gas oil. They have different curing properties (rapid curing, medium curing, slow curing), each in different viscosity grades to accomodate construction practices. Bitumen – water emulsions [32] are also made and used in rapid-, medium-, or slow-setting types, again to accommodate construction practices.

4.6. Batch Air Blowing

Batch air blowing is considered separately from the continuous process because it is used primarily in the manufacture of products that have a high softening point and are not used for paving. The geometry of the processing unit is the same as shown in Figure 9, but the flux feed-stock and the products obtained are different.

Air blowing is sometimes referred to as air conversion because chemical reactions take place, whereas in distillation the fractions are separated physically and do not react. To understand the air-conversion process better, reference is made to the major variables [33] involved (Table 2). Flux source and flux viscosity are the most important parameters, because they relate to the crude source being used and to its regulation to flux consistency during refinery distillation. Temperature, air-dispersion features, and catalysts are also control factors but are more nominal as variables. There are also five dependent variables involved, of which softening point and penetration are the most important.

Table 2. Major variables in air conversion of bitumen

Independent variables	Dependent variables
flux source or composition	softening point – penetration relationship
flux consistency	product composition
temperature of reaction	reaction rate
air rate or degree of dispersion	exothermic heat of reaction
use of catalysts	effluent losses

The batch process is best described graphically by following the temperature control as a function of time (Fig. 11). Product status and product endpoint are controlled by periodic determination of the softening point, as illustrated by the test values in parentheses in this figure. The reaction is exothermic with a differential heat of reaction of about 4 – 8 J per kilogram of bitumen per degree centigrade rise in softening point [34]. Generally this is more than needed to maintain a temperature within 200 to 270 °C throughout the blowing process; therefore, small amounts of water are injected for cooling as shown in Figure 11. The temperature of the reaction should generally be lowered toward the end of the process. This helps in stabilizing the endproduct, which otherwise tends to drop back in softening point. There are many good literature references on the subject of air blowing [35–37].

Figure 11. Batch air blowing

The relationship between softening point and penetration is the most important consideration

in batch air blowing. This is largely dependent on the composition of the flux or feed-stock and its inherent qualities (see Chapter 5). Figure 12 illustrates the relationship between softening point and penetration that results when blowing two different fluxes. In this case the coating flux has a lower viscosity than the roofers flux, which accounts for differences in blow-down characteristics (relationship between softening point and penetration). This also shows that different grades of roofing bitumen may be obtained by stopping the reaction at appropriate softening point levels. Types I through IV are normally used for built-up roofing construction [38], whereas shingle coating is used in the manufacture of prepared composition roofing (for physical properties of various roofing grades, see Table 10,).

Figure 12. Blow-down curves for roofing bitumen

5. Composition of Bitumen

Composition is readily defined by reporting the mass fractions of the major hydrocarbon types or classes contained in bitumen. Many methods have been proposed for accomplishing this [39–44] , each of which attempts to resolve the overall complexity of the mixture. For the purpose of this discussion, a method now in ASTM Standards is explained in more detail [45]. This involves separating the bitumen into four generic fractions, using dispersion and precipitation in *n*-heptane, filtration, and elution – adsorption chromatography (Figure 13). As the result of many analyses of bitumen from many sources and modes of manufacture, it becomes apparent that all bitumens contain each of these four fractions, but in different proportions. The proportions also depend on the distillation cut-point and the crude from which the bitumen is derived. Figure 14 illustrates how each of the fractions may be distributed as dependent upon cut-point. It also shows that of the three petrolene fractions, saturates decrease in quantity as distillation cuts deeper. Polar aromatics increase at the same time.

Figure 13. Scheme for separation of bitumen into four fractions

Another way of understanding the effect of distillation is to consider the composition of bitumen in various production stages: first the flux, then the paving bitumen, and finally the pitch (low penetration residuum; Table 3). As distillation progresses, the saturate and the naphthene aromatic fractions decrease, whereas the polar aromatic and asphaltene fractions increase. This shows that the first two fractions, on an average, are lower boiling than the polar aromatics, with distillation having no effect on the percentage of asphaltenes. Also, distillation increases the softening point and decreases the penetration of the bitumen residuum.

Bitumens from different crude sources have different compositions. This is illustrated in Table 4, where bitumens of the same viscosity but

from different crude sources are shown to contain different proportions of the four fractions. These differences are often related to the API gravity of the crude from which the bitumen is derived [28].

Figure 14. Distribution of fractions within bitumen
S = saturates; NA = naphthene aromatics; PA = polar aromatics; A=asphaltenes

As was indicated previously, air blowing or air conversion involves chemical changes. This is evidenced by a change in the proportion of the four fractions as the result of air blowing; see Figure 15. No significant change in the percentage of saturates is found, but there is a decrease in both naphthene aromatics and polar aromatics. Air blowing always results in a significant increase in asphaltenes. Therefore, the naphthene aromatics probably convert to polar aromatics and the polar aromatics in turn to asphaltenes. As would be expected when the total liquid fractions are decreased and the solid fractions increased, the softening point will increase and the penetration will decrease in the resulting composition.

Figure 15. Chemical changes during air blowing

5.1. Elemental Analysis and Molecular Mass

The elemental analysis of a bitumen has little significance with respect to source, mode of manufacture, or service qualities. The same is true for its average molecular mass. Small differences can be measured, see Table 5, which serve the technologist in distinguishing petroleum-derived bitumen from bitumen of other sources [46]. For example, the carbon and hydrogen contents are always typically in the range given. Nitrogen and oxygen levels are always low and insignificant. The iron and nickel contents are

also quite low, whereas the vanadium content seems to be characteristic of the origin of the crude. Bitumen from Venezuelan crudes always seems to have relatively high vanadium content, which on occasion has been used as a means of fingerprinting.

5.2. Physical, Structural, and Colloidal Aspects

The four fractions differ from each other significantly with respect to their physical characteristics. This is illustrated in Table 6, which shows that the saturates and naphthene aromatics have a relatively low density and low viscosity and thus may be classified as liquids. The polar aromatics and asphaltenes have a relatively high density and a very high viscosity, making them solids. The overall consistency of a bitumen therefore is quite dependent on the proportion of the fractions present.

Each fraction can be characterized structurally by identifying its carbon atom distribution [47] along with its molecular mass [48]. Carbon atom distribution is the normalized mass fraction of carbon atoms in each of the three types of hydrocarbon structure. Table 7 illustrates a typical example of an AC-20 bitumen; it shows that the saturates are largely made up of paraffins or paraffin chains on naphthene rings but contain no aromatic compounds. The naphthene aromatics also have a high percentage of paraffin carbons but these are present as side chains on naphthene and aromatic rings. In this case, presumably all molecules contain at least one aromatic ring; otherwise they would show up in the saturate fraction. The polar aromatic and asphaltene fractions have increasing amounts of aromatic carbon but each with appreciable amounts of paraffin carbon as side chains [49]. Minor percentages of sulfur, oxygen, nitrogen, and trace metals are also present, which are considered to have a minor effect on the structural character of the average molecule present. The range in composition generally found in an AC-20 bitumen along with the corresponding structural identities is summarized in Table 8.

Table 6. Physical characterization of the four generic fractions

Fraction	Density at 20 °C, g/cm^3	Viscosity at 60 °C, Pa · s	Physical state
Saturates	0.87	0.1	liquid
Naphthene aromatics	0.97	2.2	liquid

Asphaltenes	37	13	50	5300
Average	41	30	29	1275

Table 8. Range of composition and structural characterization of typical AC-20 fractions

Fraction	Mass fraction, %	Structures identified within fraction
Saturates	5 – 15	pure paraffins + pure naphthenes + mixed paraffin – naphthenes
Naphthene aromatics	30 – 45	mixed paraffin – naphthene – aromatics + sulfur derivatives
Polar aromatics	30 – 45	mixed paraffin – naphthene – aromatics in multiring structures + sulfur, oxygen, nitrogen derivatives
Asphaltenes	5 – 20	mixed paraffin – naphthene – aromatics in polycyclic structures + sulfur, oxygen, nitrogen derivatives

Whereas the distribution of the carbon atoms in each fraction helps in identifying the chemical structures, a colloidal description helps in explaining the role played by each fraction. Bitumens are considered to be colloids [50], [51], in which certain high molecular mass constituents are dispersed or peptized in another phase of lower molecular mass. Asphaltenes are generally considered to be the dispersed phase, with the mixture of saturates plus naphthene aromatics acting as the dispersing medium or the continuous phase. The polar aromatics may serve to protect the colloidal system by keeping the asphaltene micelles in a flocculated state. This is illustrated in Figure 16, in which the polar aromatics are shown to surround the asphaltene micelles closely. As a rule bitumen colloids are very stable and cannot be separated unless severely diluted by a nonpolar solvent, such as aliphatic C_3 to C_8 hydrocarbons. This is the initial step taken in most composition analyses, as well as in commercial solvent separation processes. Another practical aspect of the colloidal concept is in developing studies related to service characteristics. This includes adhesion to mineral aggregates, as in road building, and weathering when exposed in roofing applications.

Figure 16. Flocculated asphaltene micelles

6. Physical Properties

Physical test characteristics of bitumen are of utmost importance, not only when handling or

Table 9. Physical test characteristics of straight reduced AC-20 bitumen from various crude sources

compounding, but during its service life. The thermoplastic nature of bitumen dictates a control of temperature and viscosity throughout all stages of storage, movement, and compounding. In service, its flow properties, temperature susceptibility, low-temperature flexibility, and ductility contribute to the life of the product. The crude source from which the bitumen is derived affects all these properties. This is illustrated in Table 9, where straight reduced bitumens of the same viscosity at 60 °C but of different origin are compared. Temperature susceptibility (penetration ratio, viscosity ratio), high-temperature viscosity, softening point, and Fraass breaking point vary considerably. Properties such as hardening by the thin-film oven test and ductility relate to service qualities.

The relationship between viscosity at 60 °C and penetration at 25 °C is very useful when identifying differences between crude sources. For example, a bitumen from a single crude source at different viscosity levels will plot viscosity versus penetration as a straight line on a log-log basis. Bitumens from different sources will then show a nesting of lines at different levels and often at slightly different slopes. Considering the penetration at a given viscosity level (or viscosity at a given penetration level), a quality test characteristic dependent upon crude source becomes available [52].

Temperature susceptibility (change in consistency with temperature) is related to crude source. This is sometimes indicated by factors such as penetration index, penetration ratio, or penetration – viscosity index [53–57]. Thus it is not unusual to find that one of the above factors correlates with the penetration at 25 °C for a viscosity of 200 Pa · s at 60 °C as shown in Figure 17. Another example of this is shown in the data in Table 4 where the penetration ratio on another basis and the high-temperature viscosity directionally relate to the penetration at 200 Pa · s.

Figure 17. Penetration index (pen ratio 7 °C/25 °C) versus penetration at 25 °C for a viscosity of 200 Pa · s at 60 °C

Air-blown bitumens are represented by another set of physical properties; the bitumen grade must be identified and the softening point controlled. These bitumens are generally blown from a base residuum or a flux with a viscosity of 200 to 1000 cSt at 98.9 °C and from a crude source known to meet the end product requirements. The blowdown characteristics of such bitumens are illustrated in Figure 12 and described in Section 4.6. Table 10 shows the test limits for four grades or types of blown bitumen used in roofing applications. Blown bitumens are characterized by better temperature susceptibil-

Table 10. Physical test characteristics of air-blown bitumen for use in roofing applications

ity (as indicated by closer limits on penetration at 0 and 46 °C) and lower ductility, compared with straight reduced bitumens. These properties contribute to better flow resistance and better outdoor weathering, qualities needed for roofing applications.

Rheological Behavior Bitumen is often described as a thermoplastic material that can repeatedly soften when heated and harden when cooled. Actually it is more accurate to describe bitumen as a viscoelastic substance, that is, one that acts as a viscous liquid at ambient and higher temperatures and as an elastic solid at lower temperatures. Such qualities are referred to as rheological character or rheological behavior; they are measured in relative units of flow and deformation [58]. To the engineer, this is often described in terms of mechanical properties, that is, strain responding to an applied stress. Mechanical properties are also conveniently described by the stiffness modulus [59], which in simple terms is the ratio of tensile stress to tensile strain. How well a road bitumen aggregate mixture resists stressing and seasonal effects in part depends on the inherent characteristics of the bitumen, or on the changes that occur during refining. The time of loading on a road surface and temperature are two important independent variables that determine the stiffness.

Figure 18 illustrates how a typical AC-20 bitumen would respond to different loadings and to temperature. The duration of loading in this case varies from a long loading time (approaching that of a standing load) to a very short loading time (100-km/h vehicular traffic). As would be expected, stiffness is higher at the shortest loading time, at lower temperature, and for higher viscosity grades of bitumen. Rheological characteristics of bitumens and mechanical properties of asphalt mixes have been the subject of much research [60–62]. This is attributed to the potential in better understanding road distress problems.

Figure 18. Bitumen stiffness as a function of loading time and temperature

The viscoelastic properties of the three petrolene fractions (as described in Chapter 5) are shown in Figure 19. Here the saturates, because of their makeup of saturated hydrocarbons, are the least susceptible to temperature change. The polar aromatics on the other hand are the most susceptible and, of course, have a much higher viscosity at 25 °C. The composite mixture of the three fractions along with the asphaltenes results in a typical viscosity as represented by the asterisk in Figure 19. This again supports the classification of saturates and naphthene aromatics as liquids and of the polar aromatics and asphaltenes as solids. Again, the rheology of bitumens may be attributed to the composite effect of the viscoelastic properties of the fractions making up the bitumens.

Figure 20. Viscosity increase of thin AC-40 bitumen films by exposure to air

7. Chemical Reactions of Bitumen Surfaces

In order to test the performance of bitumen surfaces, exposure to air, water, and chemicals is investigated.

Air. Under ambient conditions bitumen oxidizes slowly depending on the specific surface it exposes. The effect is always an increase in viscosity and a higher softening point. To control the surface effect, use is made of cover aggregate or films of appreciable thickness. For example, in road building the normal 10–30-μm films of bitumen in the aggregate mixtures are protected by closely compacting the mixture. In this way, only a very small fraction of the bitumen is exposed to atmospheric air and sunlight. In roofing and waterproofing applications, the exposed films are several millimeters thick, which permits gradual weathering of top layers or microsurfaces. Alternatively, even thick films may be protected by layers of sand or fine chipping; this is mostly practiced in European countries. In all these cases the rate of diffusion of air into the composite mixture or into the thick film is substantially reduced.

Figure 21. Gain-loss relationship of petrolene fractions in sub-micron films

The increase in viscosity of exposed thin films is illustrated in Figure 20. This shows that the thinner film (5 μm) increases faster in viscosity in the case of an AC-40 bitumen at room temperature [63]. In order to understand the mechanism of thin-film oxidation better, a submicron film of each of the four generic petrolene fractions (Chap. 5) was alternately exposed to nitrogen and oxygen at a temperature of 150 °C [64] (Fig. 21). This showed that under nitrogen a weight loss (volatilization) always takes place, whereas under oxygen a weight gain predomi-

nates for both the polar aromatics and the asphaltenes with only a slight effect on the saturates and naphthene aromatics. In the original bitumen there is first a loss under nitrogen and then a gain under oxygen, apparently a composite effect.

For specification purposes the thin-film oven test was developed [65] to show how the properties of bitumen change when a relatively thick film (3.2 mm) is exposed in a tray to 163 °C for 5 h. In the rolling thin-film oven test [66], film thickness and exposure time are reduced by providing a rolling action during the test (see also Chap. 3). Both tests were developed in order to provide a reasonable control of hardening or viscosity increase as the result of hot-mix processing of bitumen. These tests are now routinely being specified on paving grades of bitumen in the United States.

Water. When bitumen and water are in permanent contact, the solubility of water in the bitumen is of the order of 0.001 – 0.01 wt %. This is partly caused by the presence of small quantities of water-soluble inorganic salts or other filler materials. Ordinarily bitumen possesses good resistance to water, although it is not completely impermeable (ca. 1×10^{-10} g cm^{-1} h^{-1} Pa^{-1}). In practical applications this is negligible because thick films or layered membranes are used.

Chemicals. Ordinarily bitumen resists reaction with mild chemicals and all environmental effects other than those described above. Bitumen reacts with aggressive chemicals. Strong sulfuric, nitric, and hydrochloric acids react to form substitution products. Dilute acids sometimes cause bitumen to harden slowly, whereas dilute bases often cause emulsification as the result of a reaction with the acidic components in the bitumen. At moderate temperature potassium permanganate and other strong oxidizing agents react similarly to air oxidation. At high temperatures these agents have the effect of fast burning. Chlorine gas reacts with bitumen at 100 °C resulting in substitution, whereas at higher temperature hydrogen chloride is formed. At 150 °C and above sulfur reacts with perceptible rate with the liberation of hydrogen sulfide, similar to the reaction with oxygen [67].

Much work has been done using small amounts of catalysts during the air-blowing operation, generally at 225 °C and above. The purpose is to provide a higher penetration at a given softening point level, or to reduce the conversion time. Iron(III) chloride and phosphorus pentoxide [68] have been used commercially for this purpose, and other agents have been suggested. Some refer to these agents as chemical reactants rather than catalysts, because they are either consumed or are converted chemically.

8. Handling and Storage

Fluidity or viscosity is the primary consideration in pumping, transporting, and storing of bitumen. Viscosity is affected by temperature and by the type and grade involved. Figure 22 relates viscosity to temperature for two cement and two air-blown grades. Also shown is a line indicating the approximate design pumpability. At higher temperatures and lower viscosities pumping is optimized, whereas at lower temperatures and higher viscosities pumping efficiency decreases rapidly. Thus viscosity and its control by temperature is an important consideration in respect to all handling operations.

Figure 22. Viscosity as a function of temperature for asphalt cements (AC-10 and AC-40) and for air-blown bitumen (85 °C softening point and 110 °C softening point) – – – Design pumpability

If bitumen is held in hot storage, certain safety considerations are advisable. For example, all bitumens, whether straight reduced or air blown, emit small amounts of light hydrocarbons (C_1 to C_4 and above) into the head-space above the hot liquid. The amount of these light hydrocarbons

emitted depends largely on the storage temperature but also on practices during manufacture. The concentration of these hydrocarbons in the headspace above the liquid also depends on venting as well as loading and unloading practices. All of this becomes a safety consideration as dependent on the concentration of the hydrocarbons, the oxygen content in the headspace, and a possible source of ignition.

The oxygen content of the headspace above the bitumen also depends on air movement into and out of the tank. The ignition source can be extraneous or from pyrophoric iron sulfides that develop from corrosion on tank walls and ceilings. More on this subject may be found in the literature [69]. With storage temperatures being an important factor affecting headspace hydrocarbons, the maximum storage temperatures that are recommended in the literature for each type and grade of bitumen should be observed [70]. Blanketing of vapor spaces with either nitrogen or fuel gas has also been effective in reducing oxygen concentrations. In view of the above, the flash point of the bituminous material should be known, but it should not be the only consideration in safe handling.

9. Uses of Bitumen

Bitumen is a primary engineering material, functioning as a binder in road construction and as a weatherproofing membrane in roofing and structural applications. Its thermoplastic nature, its water resistance, and its adhesion toward most other substances make it unique as a building material. On a volume basis it nearly equals that of lumber used in the United States and surpasses that of either steel or Portland cement. Almost every home, building, or traffic area uses bitumen in some form or other. This attests to its reasonable cost and versatile nature.

9.1. Bitumen in Road Building

Bitumen serves primarily as a binder in asphalt compacted mixes, which in turn are widely used in many types of road, street, runway, revetment, and parking area applications. Asphalt hot mixes are typically prepared either by batch mixing plants or by continuous-flow drum mixing plants. This involves the selection and grading of mineral aggregates, passing them through a heated drum mixer during which the bitumen binder is added in controlled amounts (4 – 10 wt %). Mixing is carried out at about 150 – 160 °C, after which the hot mix is transported to road sites, where it is placed and compacted on prepared bases. Traffic loads and their volumes influence the road design, that is, the thickness and type of construction used. Over 90 % of all traffic-carrying areas today are constructed with asphalt mixes.

Table 11 lists specification requirements for three asphalt cement grades commonly used in the United States today. These requirements are published by the American Association of State Highway and Transportation Officials (AASHTO); ASTM and DIN 1995 also list specifications that are very similar to these.

9.2. Industrial Uses

There are over one hundred different industrial applications or products in which bitumen is used, more than can be described here. This section, therefore, is limited to three of the largest volume applications, each being in the roofing field.

In North America *asphalt composition shingles* are now used on more than 95 % of private dwellings. These shingles consist of a glass fiber or cellulosic felt backing, coated on both sides with a filled asphalt and surfaced on the weather side with mineral granules. Whereas most of the shingles used in past years were made with organic felts, today's manufacture largely involves the use of fiberglass.

Second in importance to the above is the use of bitumen in *asphalt built-up roofing systems.* These consist of successive layers of asphalt-saturated felt, bonded together with a hot mopping of air-blown roofing-grade asphalt (Table 12). This system is applied to roof inclines from dead level up to 50 %. Whereas the present specification practice is based on the use of grades of increasing softening point, a new system has been proposed [71] based on grade control by viscosity at 71 °C.

The development of *single-ply roofing materials* has resulted in a major change in roof-

Table 11. Viscosity-graded asphalt cement

	Viscosity grade		
	AC-5	AC-20	AC-40
Viscosity at 60 °C, Pa · s	50 ± 10	200 ± 40	400 ± 80

ing design and application. This has involved a variety of materials, including polymers and rubbers, but also including those containing asphalt or bitumen. Those identified as modified asphalt, elastomer-modified asphalt or polymer-modified bitumen, are generally made into a membrane of about 4 mm in thickness. It consists of layers of glass fiber mats, glass fiber web, a polyester core, and the polymer-modified asphalt. The polymer is generally atactic polypropylene or styrene – butadiene – styrene block copolymer. This high-strength, flexible, excellent weathering membrane is packaged in rolls, from which it is placed as a single course on a prepared roof deck [72], see Figure 23. This illustrates an application technique that also requires fitting to roof appertunances (pertaining parts) with all joints and laps sealed. This innovative building material holds promise for better and longer lasting roofs on industrial and commercial type buildings.

9.3. Economic Aspects

The economic importance and the various uses of asphalt are described elsewhere in this article. Approximately 75 % is used as binder, mainly for the construction of roads, airports, and waterways. Approximately 20 % is processed into materials for roofs and related applications. The remainder is used for the production of construction proofing agents, paints and coatings, paper, rubber products, electrical cables, and other products of the electrical industry.

As a binder bitumen is almost indispensable for many industries. In the production of asphalt mixes the ratio of gravel, sand, and mineral flour to bitumen is about 20; one ton of such asphalt mixes requires about 9 L of heating oil during processing. The ratio of binder to matrix material (jute, glass fiber mats, glass fiber webs) is about one for single-ply roofing materials.

The consumption of bitumen increased enormously from the mid 1950s because of increased motorization; this changed sharply with the oil price shocks of 1974 and 1979. Asphalt demand in the industrialized countries then began

Figure 23. Application of single-ply roofing (reproduced with permission from Technicote Corp., Memphis, Tenn.)

to decrease because of the economic crisis and levelling-off of road construction and building. About 60×10^6 t of bitumen were consumed in the early 1970s, which was lowered to about 40×10^6 t in 1984. In 1982 bitumen consumption of some European countries was as follows (10^6 t):

Federal Republic of Germany	2.78
France	2.12
United Kingdom	1.96
Italy	1.40
Spain	0.85
Portugal	0.40
Sweden	0.44

In the United States the total consumption of bitumen increased since 1982 and reached 27.5×10^6 t in 1984.

10. Environmental and Workplace Exposure

The manufacture and use of straight reduced bitumen, cements, fluxes, or components does not present a problem with respect to air pollution or workplace exposure. At the refinery source each of these products is contained in tanks where vapor pressures are negligible and the emission of hydrocarbons to the atmosphere is insignificant. In the manufacture of hot mixes, blue-smoke emissions were investigated by the Asphalt Institute [73], reporting extremely low levels of potential pollutants (Table 13). All considered emissions (on a time-weighted average) were well within the air standards of the Environmental Protection Agency (EPA). Also, the standards of the Occupational Safety and Health Administration (OSHA) for workplace exposure are easily met, including the polynuclear aromatic compounds, sometimes considered important by health groups. This report concluded that "no significant air pollution or employee health problem can be expected or associated with emissions from hot preparation of asphalt paving mixtures."

Rapid- and medium-curing cutback asphalts intentionally contain from 17 to 42 % of volatile hydrocarbons in the C_7 to C_{15} range. These hydrocarbons come under the broad classification of volatile organic compounds and are considered in some states in the United States to be undesirable air pollutants. Therefore their usage is commonly restricted to the colder months of the year, November through April. This approach is gradually supplanting the old limitation of not more than 8 % of C_8 and higher aromatic compounds in the volatile portion of the cutback asphalt.

Fumes from the air-blowing process have at times constituted an odor problem. This can be resolved by incinerating all of the fumes from the process through a combustion furnace or incinerator where the burning temperature is 750 °C or higher. Some speculation still exists [74] that some of these fumes remain in the blown asphalt, and as such may be emitted when the asphalt is reheated in roofing kettles. In spite of this, an earlier survey [65] reported that petroleum work-

Table 13. Measured emissions at hot-mix asphalt plants compared with OSHA and EPA quality standards

	OSHA standards	EPA air standards	Measured emissions max. (8 samplings)
Carbon monoxide, ppm	50	9	6
Nitrogen dioxide, ppm	5	0.05	0.1
Sulfur dioxide, ppm	5	0.14	2
Hydrogen sulfide, ppm	20		1.5
Phenol, ppm	5		1
Ozone, ppm	0.1	0.08	0.1
Hydrocarbons ($C_7 - C_{14}$), ppm	500		1.5
Hydrocarbons ($C_2 - C_6$), ppm	10	0.24	1
Particulate matter, mg/m^3		0.365	7.2
Polynuclear aromatic compounds (total), mg/m^3	0.2		0.00036
Vanadium-V_2O_5 fume, mg/m^3	0.1		0.0001
Nickel and soluble nickel compounds as Ni, mg/m^3	1		0.00004
Cadmium fume, mg/m^3	0.1		0.00005
Lead and inorganic compounds, mg/m^3	0.2		0.00005

ers showed no greater incidence of disease than nonasphalt workers in similar environments.

1. Introduction

The widespread use of automobiles offers a degree of mobility to the individual that was unthinkable just a few centuries ago. However, with increasing car and truck population today it is obvious that the massive use of combustion-engine vehicles is not free of problems, one of the major problems being air pollution. In Germany in 1994 more than 50 % of nitrogen oxide and CO emissions and more than 40 % of hydrocarbon emissions originated from road traffic. A total of 4.1×10^6 t of carbon monoxide, 1.3×10^6 t of nitrogen oxides, and 0.74×10^6 t of hydrocarbons were emitted on German streets in 1994 [1]. The formation of the major pollutants in combustion engines and their impact on environmental and human health are discussed in Chapter 2.

Legal regulations limiting emissions of the major pollutants carbon monoxide, hydrocarbons, nitrous oxides, and diesel soot were passed in the 1970s in the USA and Japan and later also in Europe and most other parts of the world. As a consequence substantial improvement in air quality has been observed. For example, in California the number of smog-alert days decreased from 121 in 1977 before the introduction of catalytic converters to only one smog alert day in 1997, although car use has doubled since 1977. The 1996 regulations already reduced emissions per kilometer by 96 % compared to 1970 levels, with further improvements in 2000.

Chapter 3 gives a brief introduction to engine measures that allow reduction of emissions. While improved engine technology has led to some reduction in raw emissions, the dramatic reduction in tailpipe emissions, as reflected by the increasingly stringent legal limits, would not have been possible without the introduction of catalytic exhaust gas treatment systems [2–5]. Chapter 4 gives a general introduction to the working principle of catalytic exhaust gas treatment and especially focuses on the physical design of the catalyst system. The most effective type of catalyst system today is the three-way catalytic converter that simultaneously reduces concentrations of CO, NO, and hydrocarbons. Three-way catalysts are used with spark-ignition gasoline engines and allow the reduction of pollutant emissions by 96 % compared to the pollutant level before the introduction of catalytic converters. Three-way catalysts are described in Chapter 5.

Carbon dioxide is an unavoidable combustion product of fossils fuels and the only way to reduce CO_2 emissions from internal combustion engines is to construct more energy efficient engines. Due to its role as a major greenhouse gas and due to concerns about global warming, energy efficiency of automobiles has become a major concern for engine design. Today the most fuel efficient engines run with excess air and therefore do not allow application of the proven three-way catalyst. This poses the challenge of developing catalyst concepts that allow fuel-efficient lean-burn operation of the engine while retaining the low pollutant levels reached by three-way catalysts. Aftertreatment systems for lean exhaust gas are treated in Chapter 6.

2. Pollutant Formation and Limitation

In a combustion engine a hydrocarbon fuel is oxidized by atmospheric oxygen. Under ideal conditions only CO_2, water, and heat would be generated (Eq. 1).

$$C_mH_n + (m + 0.25n)\,O_2 \longrightarrow mCO_2 + 0.5n\,H_2O \qquad (1)$$

Under engine conditions, however, ideal combustion is impossible because of the lack of chemical equilibrium and the inhomogeneous gas phase. Typical combustion products resulting from incomplete combustion are:

- Carbon monoxide (CO), a combustion intermediate
- Unburned and partially oxidized hydrocarbons (HC)
- Oxides of nitrogen (NO_x)
- Particulate matter

Carbon monoxide (CO) is formed as an intermediate reaction product during combustion of hydrocarbons. Incomplete combustion due to low combustion temperature, lack of oxygen, or too short a reaction time leads to the emission of CO, a poisonous gas that displaces oxygen from the blood.

Hydrocarbons (HC). Incomplete combustion of hydrocarbon fuels leads to the emissions of unburned and partially oxidized hydrocarbons [6].

In spark-ignition engines hydrocarbons in the exhaust originate mainly from regions in which the flame extinguishes or regions not reached by the flame (quench zones). Typical examples are layers near the combustion chamber walls and crevices, e.g., in the piston ring groves (wall quenching). With very lean mixtures, the flame can extinguish prematurely (flame quenching) at the end of the expansion because of low gas temperatures in the combustion chamber. In highly turbulent mixtures, exhaust gas can surround combustible gas zones before they are reached by the flame front. The HC emissions rate can be largely caused by the combustible gas losses in two-stroke gasoline engines and, to a lesser extent, in supercharged four-stroke engines.

In compression-ignition engines, HC emissions originate in the outer zones of the injection spray, where the fuel has thoroughly mixed with air to produce an nonignitable mixture. Emissions also result from the spray center, which has a very rich mixture, as well as from the chamber wall areas. Finally, near the end of the expansion, fuel vaporizes out of the injection nozzle.

The hydrocarbons emitted from internal combustion engines are always a mixture of various compounds: paraffins, olefins, acetylenes, and aromatics. The composition depends on the combustion system, the operating conditions of the engine, and the fuel.

Oxides of nitrogen (NO_x) are generated at combustion temperatures by oxidation either of atmospheric nitrogen or nitrogen contained in the fuel. During the combustion process mainly NO is formed; NO_2, which is more toxic than NO, is formed by the relatively slow oxidization of NO in the atmosphere. In combustion processes with an excess of air significant NO_2 can be expected. NO_x reacts with hydrocarbons in sunlight to form ozone and photochemical smog. NO_x can increase respiratory illnesses and is a contributor to acid rain. Tropospheric ozone causes breathing difficulties and damages plants. In the upper atmosphere NO_x is involved in a catalytic cycle that leads to the destruction of the ozone layer.

Three mechanisms of NO_x formation must be considered [7]:

1) Thermal NO_x
2) Prompt NO_x

3) Fuel NO_x

Fuel NO_x. Fossil fuels contain organic nitrogen compounds (e.g., amides, amines, heterocyclic compounds) in concentrations of $< 1\,\%$ (coals have higher concentrations). Equation (2) is an example of such a reaction pathway.

$$\mathrm{C}_n\mathrm{H}_m\mathrm{NH}_2 + \left(n + \frac{m}{4} + 1\right)\mathrm{O}_2 \longrightarrow \tag{2}$$

$$n\mathrm{CO}_2 + \left(\frac{m}{2} + 1\right)\mathrm{H}_2\mathrm{O} + \mathrm{NO} \tag{2}$$

Thermal NO_x. The direct oxidization of N_2 by oxygen at high temperatures, the so-called thermal NO_x mechanism, was first described by Zeldovic. At temperatures above 1300 °C NO is formed by the following reaction sequence:

$$\mathrm{O} + \mathrm{N}_2 \longrightarrow \mathrm{NO} + \mathrm{N} \tag{3}$$

$$\mathrm{N} + \mathrm{O}_2 \longrightarrow \mathrm{NO} + \mathrm{O} \tag{4}$$

In rich zones of the flames (oxygen deficiency) the following reaction takes place above 1300 °C:

$$\mathrm{N} + \mathrm{OH} \longrightarrow \mathrm{NO} + \mathrm{H} \tag{5}$$

The amount of NO formed largely depends on:

- The air-to-fuel ratio in the combustion zone
- The temperature in the combustion zones
- The time for which the reaction partners remain at combustion temperature

Prompt NO_x. Fenimore described a mechanism in which reactive radicals formed during hydrocarbon combustion react with molecular nitrogen to form NO:

$$\mathrm{CH} + \mathrm{N}_2 \longrightarrow \mathrm{HCN} + \mathrm{N} \tag{6}$$

$$\mathrm{C} + \mathrm{N}_2 \longrightarrow \mathrm{CN} + \mathrm{N} \tag{7}$$

$$\mathrm{CN} + \mathrm{H}_2 \longrightarrow \mathrm{HCN} + \mathrm{H} \tag{8}$$

$$\mathrm{CN} + \mathrm{H}_2\mathrm{O} \longrightarrow \mathrm{HCN} + \mathrm{OH} \tag{9}$$

$$\mathrm{HCN, CN} + \mathrm{O} \longrightarrow \mathrm{NO} + \text{organic residue} \tag{10}$$

This mechanism requires rich combustion conditions and therefore does not play a significant role in a well-controlled engine combustion processes.

Particulate Emissions. Particulates are tiny solid and liquid particles. They occur in the exhaust of diesel engines in sizes from 0.01 to 1 µm and consist of carbon-rich particles (soot), hydrocarbons, and sulfates. In a diesel engine, due to incomplete mixing, zones of air deficiency arise and lead to soot formation. In parallel, in zones with excess air, soot is partially burned. Soot emissions are strongly increased if the air – fuel mixture is enriched to near stochiometry.

Recent research has shown that especially ultrafine particles (< 100 nm in mean diameter) and nanosized particles (< 50 nm in mean diameter) are potentially dangerous due to their capability to enter deep into the respiratory tract. Furthermore, these small particles supposedly can penetrate cell membranes.

Carbon Dioxide. Carbon dioxide (CO_2), although the most commonly emitted combustion gas, is normally not considered as a pollutant since adverse health effects are not known. However, CO_2 should be regarded as a serious pollutant in terms of its global-warming potential. CO_2 has been identified as a greenhouse gas, i.e., a gas-phase species with strong infrared adsorption bands that lets short-wavelength light from the sun pass through but adsorbs the light reflected from the earth in the troposphere. Due to the large CO_2 emission rate and its long lifetime its contribution to the greenhouse effects is estimated to be 50 %. Since CO_2 is an intrinsic reaction product of fuel combustion, the only way to reduce CO_2 emissions is to improve fuel economy.

Sulfur Compounds. Any sulfur contained in the fuel is emitted through the tailpipe in the form of sulfur compounds, mostly as SO_2. Under atmospheric conditions the SO_2 is oxidized to SO_3, which leads to the formation of sulfuric acid. Sulfuric acid originating from the combustion of sulfur-containing fuels is a major contributor to acid rain. Currently the only feasible way to reduce emissions of sulfur compounds from internal combustion engines is to reduce the sulfur content of the fuel.

If the engine is operated under rich conditions SO_2 can be reduced to H_2S in the catalytic converter. Since H_2S has a characteristic unpleasant smell, it is the task of the engine manage-

ment system to avoid driving conditions that lead to the formation of significant concentrations of H_2S.

3. Developments in Engine Technology

Engine technology is a wide field and is not the main focus of this article. For this reason here only a few developments in engine technology that have direct impact on catalytic emission control are outlined. A more complete treatment of the development of engine technology can be found elsewhere [8].

Traditionally diesel engines show some advantage in fuel economy compared to spark-ignition gasoline engines. The fuel economy of diesel engines was recently improved even further by the introduction of high-pressure direct-injection technologies, so that today the diesel engine exhibits an advantage in fuel economy over the conventional gasoline engine of about 25 – 30 %.

Several effects contribute to the fact that conventional gasoline engines show poorer fuel economy than diesel engines, the major reason being that these engines must be run with a stochiometric air – fuel mixture and that at low load the air intake of the engine has to be adjusted to the fuel by placing a throttle in the air intake. Especially at low load the throttle creates a vacuum in the intake manifold that imposes extra work on the cylinders. Other effects that contribute to the limited efficiency of current gasoline engines are temperature loss to the walls and friction. Several possibilities exist to improve the fuel economy of gasoline fuel cars, all of which try to minimize the energy inefficiency caused by the operation of the throttle at low engine load:

- Downsizing
- Electromechanical valve control
- Direct injection

The operating points met in urban driving can be shifted towards the more fuel efficient high-load region by downsizing the engine. To retain the same overall maximum power the specific power of the downsized engine must be increased by supercharging the engine. Best fuel economy at low load is obtained if a turbocharger with variable compression ratio is used.

An alternative technology is electromechanical valve control. Here the valves can be controlled individually and independent of the cylinder movement so that the air intake can be controlled by the timing of valve opening instead of the energy-inefficient throttle. Both downsizing and electromechanical valve control operate the engine with a stochiometric air – fuel mixture and therefore can be used in combination with the well-established three-way catalyst. The improvement in fuel economy expected from these technologies is limited to about 15 % relative to conventional gasoline engines.

Ultimate improvements in fuel economy can probably only be achieved if direct injection or combinations of the above-mentioned technologies with direct injection are employed. In a gasoline direct-injection engine the fuel is directly injected into the cylinder. like in diesel engines. This allows operation of the engine with an oxygen-rich air – fuel mixture under partial load. In this way the disadvantages related to throttling the air intake can be completely avoided. Additional fuel economy is gained because modern gasoline direct-injection engines minimize wall heat losses and cylinder friction. Due to the lean operation at partial load, exhaust from a gasoline direct-injection engine can not be cleaned with a conventional three-way catalyst. New catalyst technologies must be developed for the treatment of the lean-burn direct-injection gasoline exhaust. Catalysts for the treatment of lean exhaust from gasoline lean-burn and diesel engines are described in Chapter 6.

4. Catalytic Exhaust Aftertreatment, General Concepts

Even though advanced engine technology offers substantial potential for the reduction of emissions of hazardous compounds, engine improvements alone do not allow a reduction of emissions to a level necessary to fulfill current and future emission legislation. For this reason aftertreatment of the raw exhaust gasses emitted by the engine is unavoidable. Under typical operation conditions the thermodynamic equilibria for the main reactions transforming exhaust gas

pollutants into harmless compounds are on the product side, so that automotive exhaust purification essentially is a kinetic problem. For this reason catalysts that enhance the reaction rates are the method of choice for exhaust aftertreatment [2–6].

4.1. The Physical Design of the Catalytic Converter

Figure 1. Various designs of emission control catalysts (beads, ceramic monoliths, metal monliths)

Exhaust gas catalysis is a heterogeneous surface process, and to reach acceptable conversion within a reasonable catalyst volume a carrier structure must be used that exposes the exhaust gas flow to a high geometric surface area. In the early days of exhaust gas catalysis pellets were used for this purpose. In recent years pellets have been completely replaced by monolithic honeycomb carrier structures. Monolithic converters consist of a single body that possesses a multitude of parallel channels, with the catalytically active material deposited along the walls of the channels. Figure 1 shows various designs of emission control catalysts. Honeycomb converters exhibit several advantages over pellet converters, the most important being the lower pressure drop and the reduced complexity of the converter housing design. A typical converter design with a ceramic monolith is shown in Figure 2.

Monolithic supports are produced either from ceramic or metal, each of which has specific advantages.

Ceramic monoliths are most commonly produced by an extrusion process from synthetic corderite $2\,MgO{\cdot}2\,Al_2O_3{\cdot}SiO_2$. This material has a number of advantageous properties for this application, such as high melting point ($>1300\,°C$), high mechanical strength, and most importantly a very low thermal expansion coefficient that results in excellent thermal shock resistance. Ceramic supports can be produced in a variety of different forms that differ in their outer dimensions, cell shape, cell density, and wall thickness. Today the most commonly used supports have square channels, a cell density of about 62 channels per square centimeter, and a wall thickness of about 0.15 mm. Thinner walls increase the open frontal area and accelerate heating up during vehicle start. Higher cell densities improve the geometrical contact surface within the channels. For these reasons there are ongoing efforts to develop supports with thinner walls and higher cell densities.

Figure 2. Design principle of a ceramic monolithic based converter for aftertreatment of exhaust gases

In the few last years monoliths made of metal were introduced to the market. Their main advantage is that they can be prepared with thinner walls. This allows higher cell densities with increased frontal area and thus reduced pressure drop. The low heat capacity of the thin metal walls and the higher thermal conductivity result in faster heat up compared to ceramic catalysts. However, metals are prone to corrosion under exhaust conditions, and their thermal expansion behavior is less compatible with the catalytic material.

4.2. The Washcoat

Ceramic and metallic monolith structures have a geometric surface area in the range of $2.0-4.0\,m^2$ per liter of support volume. This is much too low to adequately perform the catalytic conversion of the exhaust gas components. For this reason the monolith channel walls are coated with a thin layer of inorganic oxides with a very high internal surface area. This layer of carrier oxides is called the washcoat. The washcoat enhances the surface of the catalyst by a factor of about 10 000. Figure 3 shows individual channels of a ceramic monolith coated with washcoat. The main components of the washcoat are inorganic oxides and mixed oxides, and it also contains the catalytically active metals, mainly the platinum group metals (PGMs) Pt, Pd, and Rh, for which the oxides act as a support.

Figure 3. Close-up view of a washcoated ceramic monolith

The inorganic carrier oxides serve several functions vital for operation of the catalytic converter. First, they must maintain a high surface area even under severe aging conditions at temperatures above 1000 °C. Second, the carrier oxides have to prevent the catalytically active precious metal particles from sintering to larger particles at high temperatures. This is accomplished by tailoring the oxide composition such that the precious metal particles are tightly bonded on the carrier oxide surface. Figure 4 shows a high-resolution transmission electron micrograph of washcoat particles with finely dispersed PGM particles. Third, the carrier oxide improves the catalytic function of the precious metal particles by favorable electronic interaction between the precious metal clusters and the carrier oxide surface. To fulfill all these requirements modern washcoat systems are very complex chemical systems. The washcoat matrix consists of specifically designed mixed crystal lattices, and various chemically different phases are selectively combined to optimize performance and selectivity. The manufacturing process controls the optimum placement of the precious metals with respect to primary particle size and location on the different carrier phases.

Figure 4. Transmission electron micrograph of PGMs on a washcoat particle

Alumina is the most common carrier oxide used in automotive exhaust gas catalysis. Typically γ-, δ-, and θ-Al_2O_3 are used with internal surface areas of $50-250\,m^2\,g^{-1}$. Frequently the Al_2O_3 is doped with rare earth or alkaline earth elements. The role of the dopant is to increase the aging stability of the carrier and to optimize the carrier – precious metal interaction to prevent precious metal sintering and to enhance the catalytic activity of the precious metal particles. Besides alumina other common washcoat constituents are cerium and zirconium oxides. Cerium oxide mostly serves an oxygen storage component (see Section 5.2). Recently, zirconium cerium mixed oxides with optional additional dopants have been used.

The washcoat is usually prepared as an aqueous slurry and applied to the monolithic carrier by a dipping or spraying process followed by blowing out of excess washcoat slurry, drying, and calcination. Tight process and materials control is essential due to the high cost of the ingredients, especially the PGMs.

5. Catalytic Aftertreatment of Stoichiometric Exhaust Gas

Up to now the majority of passenger cars and light-duty vehicles, especially in the USA, are propelled by spark-ignition engines operated under stoichiometric conditions. Due to their large population and, compared to diesel engines, their high raw emissions these vehicles accounted for a large part of the air pollution in urban areas. Therefore, spark-ignition engines were the first to require catalytic exhaust aftertreatment to fulfill emissions regulations. Most of the commercial experience in automotive catalysis till now has been gained in the field of stochiometric spark-ignition engines.

Different concepts of catalytic pollution control for stoichiometric spark ignition engines have been used over time (Fig. 5). During an initial period following the introduction of precious metal exhaust gas catalysts in 1975, NO limits could be reached by engine measures such as exhaust gas recirculation, and legislation only required the treatment of CO and HC. At this time engines were run slightly rich to reduce NO emissions. Secondary air was injected in front of the catalyst (Fig. 5 A), and the catalyst was subjected to oxygen-rich exhaust gas so that CO and hydrocarbons could be oxidized by the following reactions:

$$2\,CO + O_2 \longrightarrow 2\,CO_2 \tag{11}$$

$$C_mH_n + (m + 0.25n)\,O_2 \longrightarrow m\,CO_2 + 0.5n\,H_2O \tag{12}$$

The next step in legislation in 1977 called for a reduction in nitrogen oxides. For this purpose a reduction catalyst was introduced that operated directly on the CO- and hydrocarbon-rich exhaust gas and removed nitrogen oxide by the reactions:

$$CO + NO \longrightarrow 0.5\,N_2 + CO_2 \tag{13}$$

$$C_mH_n + (2m + 0.5n)\,NO \longrightarrow m\,CO_2 + 0.5n\,H_2O + (m + 0.25n)\,N_2 \tag{14}$$

Secondary air was injected downstream of the reduction catalyst (Fig. 5 B), and CO and hydrocarbon emissions were reduced by an additional oxidation catalyst.

Figure 5. Processes for catalytic automotive-exhaust purification
A) Single-bed oxidation catalyst; B) Dual-bed catalysis; C) Three-way catalyst with closed-loop control

A further improvement in exhaust gas control technology for stoichiometric spark-ignition engines was achieved by the development of three-way catalysts that simultaneously convert all three regulated pollutants.

5.1. Three-Way Catalysis

In Figure 6 the conversion efficiencies of a typical closed-loop three-way catalyst (Fig. 5 C) for the major pollutants are plotted as a function of the normalized air to fuel (A/F) ratio lamba. Under oxygen-rich conditions ($\lambda > 1$) CO and hydrocarbon conversions are high, while NO conversion is prevented by insufficient supply of reductants. Under fuel-rich conditions ($\lambda < 1$) the catalyst shows high NO conversion but low conversion of CO and hydrocarbons. The conversion ranges for NO and CO/hydrocarbons overlap at $\lambda = 1$. In a small λ range around stoichiometry the catalyst exhibits acceptable conversion for all three pollutants. Efficient operation of the

three-way catalyst requires the engine to be run exactly within this λ window at all times and was therefore only made possible by the introduction of λ sensors and active-feedback λ control.

Figure 6. Range of λ values in which various catalytic aftertreatment concepts are operated
A) Single-bed oxidation catalyst; B) Dual-bed catalysis; C) Three-way catalyst with closed-loop control

The λ sensors applied for feedback control of A/F ratio are electrochemical solid-state sensors that measure the concentration of free oxygen after complete conversion of the exhaust gas mixture on a catalytically active layer coated on the sensor element. The active material of the sensor itself is the anion conductor ZrO_2, and the potential between a reference gas and the exhaust gas across the ZrO_2 is determined by the equilibrium concentration of free O_2 after complete conversion on the catalytic surface of the λ sensor [4]. The λ sensor gives a signal of about 50 mV at $\lambda > 1$, and about 800 mV for $\lambda < 1$ with a sharp jump at $\lambda = 1$. In a basic design of a three-way catalytic system, a λ sensor is situated in the exhaust gas before the catalytic converter and returns a feedback signal which is used to control the electronic fuel injection such that derivations from $\lambda = 1$ are compensated.

5.2. Oxygen Storage in Three-Way Catalysts

Due to the finite time response of the feedback control the A/F ratio in the feedback-controlled mode performs regular λ variations around $\lambda = 1$. These perturbations occur with a frequency around 1 Hz and an amplitude of about 1 – 10 % of the A/F set point. Comparison with the conversion plot in Figure 6 reveals that A/F variations of 1 – 10 % are large compared to the width of the three-way conversion window, and that during such perturbations the A/F value is outside the optimal range for most of the time.

For this reason three-way catalysts contain oxygen components that buffer the A/F variations. The compound most commonly used for this purpose is CeO_2. The redox transition between Ce^{IV} and Ce^{III} acts as an oxygen buffer [9]. During lean excursions Ce_2O_3 is oxidized by excess O_2, and this results in the desired correction of the gas phase A/F ratio towards stoichiometry.

$$Ce_2O_3 + 0.5\,O_2 \longrightarrow 2\,CeO_2 \tag{15}$$

In a susequent rich excursion the stored oxygen in turn is used to oxidize the excess CO and hydrocarbons, again shifting the gas phase composition towards stoichiometry.

$$2\,CeO_2 + CO \longrightarrow Ce_2O_3 + CO_2 \tag{16}$$

Later it was discovered that ZrO_2/CeO_2 mixed oxides show superior O^{2-} ion mobility than pure CeO_2 and hence have improved oxygen-storage behavior, and the oxygen-buffer performance can be further improved by doping with additional rare earth elements. For this reason in modern three-way catalysts pure CeO_2 has been widely replaced as an oxygen storage material by specifically designed mixed crystal lattices.

A further benefit of including CeO_2 or CeO_2/ZrO_2 mixed oxides in the washcoat is their ability to catalyze the water gas shift and steam reforming reactions:

$$CO + H_2O \longrightarrow CO_2 + H_2 \tag{17}$$

$$C_mH_n + (2m)\,H_2O \longrightarrow m\,CO_2 + (2m + 0.5n)\,H_2 \tag{18}$$

These reactions contribute to the removal of CO and hydrocarbons, and the H_2 acts as a very active reductant for NO:

$$NO + H_2 \longrightarrow 0.5\,N_2 + H_2O \tag{19}$$

Due to the presence of oxygen storage components λ fluctuations at the exit of the three-way catalyst are by far less pronounced than upstream of the catalyst. Consequently, a λ sensor downstream of the catalyst is perturbed to a

much lesser extent by λ fluctuations and allows more precise determination of the long-term average A/F ratio. For this reason modern engine management systems use a dual λ sensor concept. A front sensor located upstream of the catalyst is used for short-term λ feedback control, and a second, rear sensor located downstream of the catalyst in a secondary control loop controls the long-term average A/F ratio.

Current regulations require the performance of the exhaust gas converter system to be continuously monitored during vehicle operation. Ideally this on board diagnostics (OBD) requirement would be fulfilled by directly monitoring the output of one or several of the regulated pollutants. However, currently detectors for the major exhaust gas pollutants are expensive and voluminous devices, and there are no sensors available that from the point of view of cost, space requirements, and sensitivity are suitable for use in serial-production three-way catalytic converter systems. For this reason legislation currently accepts the monitoring of oxygen-storage capacity as an indicator of catalyst performance. The idea behind this is that oxygen-storage capacity is a key factor determining the performance of the three-way catalyst system and that major catalyst aging mechanisms impact oxygen-storage capacity in approximately the same way as the catalytic performance of the catalyst. Generally, on board diagnostics for the oxygen-storage capacity use a dual λ sensor configuration. A common scheme makes use of the natural λ fluctuations imposed by the A/F feedback control and determines the oxygen-storage performance from the comparison of up- and downstream modulation amplitude, phase shift, or related quantities.

5.3. Precious Metals in Three Way Catalysis

Much effort has been spent on replacing platinum group metals by less expensive and more abundant materials. Numerous publications describe the results obtained with catalysts that contain, for example, the oxides of Cu, Cr, Fe, Co, and Ni. However, until today no breakthrough has been achieved, and automotive exhaust treatment still relies on precious metals, mostly Pt, Pd, and Rh, as catalytically active components. Each of these three major precious metals has specific advantages and disadvantages.

Platinum and palladium are generally used for oxidation catalysts and to promote the oxidation reactions (11) and (12) in three-way catalysts. The characteristic advantage of Pt over Pd is its higher resistance to poisoning by sulfur and lead. This promoted the preferred use of Pt in the early days of exhaust gas catalysis.

The specific advantage of Pd is its higher resistance to high-temperature aging, especially under oxygen-rich conditions, and its better performance at lean cold start. Both make Pd the precious metal of choice for close-coupled start catalysts. One drawback associated with the use of Pd in three-way catalysts is that its three-way conversion window is generally narrower. This difficulty could be overcome by improved λ feedback control and specifically designed washcoat compositions.

Rhodium is employed in three-way and reduction catalysts due to its superior performance in promoting the NO reduction reactions (13) and (14) and its high selectivity for the formation of N_2 in these reactions, whereas Pt and Pd tend to form NH_3 and N_2O.

A combination of technical and price considerations led to the preferred use of different precious metals for different generations of three-way catalysts. In the early days of three-way catalysis there was no alternative to the application of Pt or Pt/Rh catalysts due to the contamination of the fuel with sulfur and lead. Starting from about 1980 preferences shifted towards Pd/Rh or even Pd-only systems. This can be explained by the increased fuel quality and by the relatively low price of Pd at that time. More recently, due to the high demand from the automotive catalyst industry, the cost advantage of Pd-based systems has disappeared, and interest has focused again on Pt-based systems. In general, the supply situation is considered more critical for Pd than for Pt, since Pd is a byproduct of Ni production, so that Pd production does not flexibly adjust to changes in Pd demand, while Pt production capacity, at least in the long term, is expected to increase according to the growing demand.

5.4. Recent Developments in Three-Way Catalysis

Today three-way catalysts, after having reached their operating temperature, show very high conversion of the major polutants CO, HC, and NO. More than 80 % of the overall emissions, especially of the hydrocarbon emissions, occur during the warm-up phase directly following the cold start of the vehicle. Consequently, the key to further reductions of overall emissions is to improve the cold-start performance of the catalytic converter.

One approach to accelerate the warm-up of the catalytic converter is to employ a start catalyst that is mounted very close to the outlet of the engine and is therefore heated very rapidly after starting the engine. This close-coupled catalyst can either be used in addition to or can even completely replace the traditional underfloor catalyst. Due to the high temperatures encountered in the close-coupled position, very temperature resistant washcoat formulations had to be developed for this application.

An alternative approach is to actively heat the catalyst, either electrically or by a burner system mounted in front of the catalyst. A general drawback of actively heated catalytic converters is the high cost associated with these systems.

A third approach to reduce hydrocarbon emissions during cold start is the application of hydrocarbon adsorption traps. Here during cold-start hydrocarbons are adsorbed by an adsorber material, generally a zeolite. When the catalytic converter has reached a higher temperature, the hydrocarbons are desorbed and converted on the catalyst. Hydrocarbon adsorber systems are frequently employed in combination with actively heated catalysts.

6. Catalytic Aftertreatment of Lean Exhaust Gas

Diesel engines and lean-burn gasoline engines become more and more important due to current efforts to increase fuel economy and reduce emissions of the greenhouse gas CO_2. The oxidation of the pollutants CO and hydrocarbons is in principal facilitated by the excess of oxygen in lean exhaust gas. However, NO reduction on Rh is inhibited by high oxygen concentrations. This makes NO_x removal the technical challenge in the treatment of lean exhaust gas. Several strategies have been developed to remove NO_x from lean exhaust gas. In principle these strategies can be applied for diesel and gasoline lean-burn engines. Consequently, first the different techniques for NO_x removal under lean conditions are discussed, followed by sections treating the specific problems and solutions associated with gasoline lean-burn and diesel engine operation, including the additional measures necessary to control soot emissions from diesel engines.

6.1. NO_x Removal from Lean Exhaust Gas

$DeNO_x$ Catalysts. Certain catalyst materials are known to selectively promote the reduction of NO by hydrocarbons even in the presence of excess oxygen. Two classes of $DeNO_x$ catalysts have been intensively studied: zeolites exchanged with transition metals (typically Cu/ZSM-5) and platinum group metals.

One major difficulty encountered with $DeNO_x$ catalysts is their relatively narrow temperature window of operation: At low temperatures conversion is too slow, while at higher temperature the selectivity is lost, and hydrocarbons are consumed by reaction with excess oxygen.

In the following list of starting compounds for direct dyes, recent results compiled from the patent literature have been taken into account in particular in the compounds listed under (b) and (e).

Further technical problems are caused by the limited temperature stability of current catalysts. This requires the catalysts to be positioned in an underfloor position and limits the light-off performance of the converter system.

Efficient conversion of NO_x requires the presence of HC in high enough concentrations. One option is to increase the hydrocarbon concentration in the raw exhaust by appropriate adjustment of the injection timing. This configuration exhibits severe problems in meeting HC limits, especially during start up of the vehicle, because it is not possible to use a start-up oxidation catalyst close to the manifold. Alternatively, injection of secondary fuel into the exhaust line upstream of the $DeNO_x$ catalyst can be used.

Due to the technical problems associated with the application of $DeNO_x$ catalysts the system is currently not widely used in serial applications. One exception are the first-generation gasoline direct injection vehicles that are sold in Japan, which use specially developed $DeNO_x$ catalysts based on iridium as the catalytically active material.

Selective Catalytic Reduction with Ammonia. Selective reduction of NO_x by NH_3 is a well-established process for the exhaust treatment of stationary sources. In this process NH_3 or an appropriate precursor is added to the exhaust gas, and a catalyst promotes the selective reduction of NO by NH_3 in the presence of excess O_2 by the following reaction [10]:

$$NO + NH_3 + 0.25\,O_2 \longrightarrow N_2 + 1.5\,H_2O \tag{20}$$

For automotive applications NH_3 is generated on board by catalytic or thermal decomposition of urea, a nontoxic and relatively easy to handle chemical. The amount of NH_3 added to the exhaust stream must be matched to the engine NO emission at each operating point. Vehicle tests have shown that this technology possesses promising potential, at least for applications with heavy-duty truck diesel engines.

Initially, the introduction of NH_3 SCR has met some resistance, mainly because of the need to handle and store a chemical on board, and because of the expenses associated with building a new infrastructure to distribute it. However, it is now becoming apparent that the advantages inherent to the system, mainly the possibility to reduce NO_x and simultaneously optimize fuel economy and particulate emissions, may well outweigh the disadvantages. It is expected that NH_3 SCR will be introduced into heavy duty truck serial production starting from about 2005. A typical system for onboard NH_3 selective catalytic reduction is shown in Figure 7.

The NO_x Adsorber Catalyst. The operating principle of NO_x absorbers is based on the fact that highly basic alkaline earth and alkali metal oxides form stable nitrates at temperatures below about 600 °C. In an NO_x adsorber/converter system NO is first oxidized to NO_2, which then reacts with the basic oxides in the adsorber to form a nitrate. Oxides frequently employed for this purpose are BaO and K_2O. For BaO the reaction reads:

$$BaO + 2\,NO_2 + \tfrac{1}{2}\,O_2 \longrightarrow Ba(NO_3)_2 \tag{21}$$

Of course, the storage capacity of the oxide is soon exhausted and the storage catalyst must be regenerated. For this purpose the engine is switched to rich operation for a few seconds. Finely divided precious metal on the adsorber catalyst promotes the reduction of nitrate by CO, hydrocarbon, or H_2 to form N_2:

$$Ba(NO_3) + 5\,CO \longrightarrow BaO + 5\,CO_2 + N_2 \tag{22}$$

$$Ba(NO_3)_2 + 5\,H_2 \longrightarrow BaO + 5\,H_2O + N_2 \tag{23}$$

In this way the oxide is reformed and can serve as NO_x adsorber during the following cycle of lean operation (Fig. 8). The regeneration cycle is triggered by the engine management computer system that monitors the NO_x level of the adsorber catalyst either by model-based computation of the total NO_x fed into the adsorber during each cycle or by applying a sensor downstream of the adsorber. For this reason the adsorber catalyst becomes an integral part of the engine- and fuel-management system.

Currently the major technical problem associated with the application of NO_x storage catalysts is the adsorption of sulfur oxides by the same mechanism as NO_2. Since the resulting sulfates, owing to their higher stability, are not destroyed in an average rich regeneration cycle, sulfur accumulates on the catalyst and lowers the NO_x adsorption capacity. For this reason the catalyst must be regenerated from sulfur from time to time, e.g., by running the engine rich at elevated temperatures for several minutes. The sulfur regeneration cycle is fuel-expensive, and since the execution frequency of the cycle is determined by the fuel sulfur content a high sulfur concentration directly translates into a corresponding fuel penalty during operation of the NO_x adsorber catalyst.

6.2. Catalytic Aftertreatment of Lean-Burn Gasoline Exhaust

Catalytic converters for direct-injection lean-burn engines are derived from three-way catalyst

Figure 7. A typical system for NO_x control by area onboard SCR

Figure 8. NO_x storage cycle

systems [11]. However, under the operating conditions when the engine is operated at lean burn the three-way converter does not convert NO. For this reason special measures must be taken to allow NO conversion under oxygen-rich conditions. The different strategies of NO treatment in lean exhaust gas are described in Section 6.1.

The first direct-injection lean-burn vehicles offered on the Japanese marked were equipped with special $DeNO_x$ catalysts (see Section 6.1) based on iridium as the catalytically active material. However, such systems do not exhibit high enough temperature stability to withstand the severe aging conditions during U.S. and especially European driving.

Currently, the preferred technology for NO_x treatment of gasoline direct-injection lean-burn engines is the NO_x absorber. A typical converter system for gasoline lean burn exhaust gas treatment is shown in Figure 9. The exhaust gas first

Figure 9. Aftertreatment system for a gasoline direct-injection engine

passes through a start catalyst that removes CO and hydrocarbons during light off and oxidizes NO to NO_2. The start catalyst is followed by the NO_x adsorber catalyst and a conventional three-way catalyst.

6.3. Catalytic Aftertreatment of Diesel Exhaust

Compared to gasoline engines, diesel catalytic exhaust treatment is complicated by two additional problems: the relatively high sulfur concentration in diesel fuel and the emission of soot and other particulate matter by diesel engines. For these reasons, and because of the intrinsically lower gaseous pollutant concentrations compared to spark ignition engines, catalytic aftertreatment for diesel engines was implemented much later than for spark-ignition vehicles. The only diesel exhaust technology widely used in serial applications today is the diesel oxidation catalyst. This technology has been generally applied to passenger cars in Europe and to some medium- and heavy-duty trucks in the USA since about 1991.

The function of a diesel oxidation catalyst is the reation of CO and hydrocarbons with the excess oxygen in the diesel exhaust (reactions 11 and 12). Additionally the mass of particulate matter is reduced by the oxidation of liquid and polynuclear aromatic hydrocarbons adsorbed on the particulates. Though diesel oxidation catalysts use washcoats that are similar to those in three-way catalysts, technical requirements are very different for diesel oxidation catalysts, and washcoat compositions optimized to meet these requirements have been developed.

The key is to design a catalyst that selectively catalyzes the oxidation of CO and hydrocarbons and simultaneously suppresses the oxidation of NO and SO_2. Especially SO_3 formation must be avoided because SO_3 deactivates alumina-based washcoats by the formation of sulfates and because SO_3 condenses as sulfuric acid on the particulates and thus increases their mass.

One additional problem faced in diesel exhaust catalysis is clogging of the monolith channels by accumulation of particulate matter. This problem is generally solved by applying monoliths with higher cell diameter.

Thermal aging is a less severe problem with diesel catalysts because of the intrinsically lower exhaust temperature of diesel engines. However, due to the low temperature of diesel exhaust, diesel oxidation catalysts must be optimized to become catalytically active at very low temperatures, frequently below 150 °C.

Until today none of the NO_x removal technologies described in Section 6.1 has found wide use in diesel vehicles. NO_x adsorber catalysts and $DeNO_x$ catalysts are very sensitive to fuel

sulfur and for this reason can not be used at current diesel sulfur levels. However, current diesel oxidation catalysts, depending on the design of the washcoat, show some degree of NO_x conversion. For this reason there is not a clear distinction between diesel oxidation catalysts and $DeNO_x$ catalysts.

Ammonia SCR is expected to be introduced for heavy duty trucks by about 2005. The advantage of this technology is that it allows the engine to be run under conditions where fuel economy is optimized and particulate emissions are reduced to a minimum.

6.4. Removal of Particulate Emissions

Besides NO, CO, and hydrocarbons diesel engines emit particulate matter as a fourth major regulated pollutant. In contrast to the catalytic removal of the gaseous pollutants removal of particulate matter is a physical separation process. The exhaust gas is forced to flow through a filter material with pores smaller than or similar in size to the particles, which are trapped within the pores or on the surface of the filter. The currently most common design for particulate filters is the wall-flow monolith design (Fig. 10). This design is derived from the flow-through monoliths used for catalytic exhaust treatment by plugging the channels alternatively at the inlet and at the outlet of the monolith. In this way the exhaust gas is forced to flow through the porous walls of the monolith and the particulate matter is deposited along the walls.

Figure 10. Wall-flow monolith particulate filter

Since accumulated particulate matter blocks the pores of the trap and causes excessive pressure drop, the filter must be regenerated by burning the trapped particulate matter with the oxygen present in diesel exhaust. Ignition of the trapped particulate matter requires temperatures above about 550 °C. Such temperatures are rarely reached in the exhaust of diesel vehicles. One solution to this problem is to apply filter traps that catalytically lower the ignition temperature of the soot. Regeneration of the particulate trap at temperatures below about 300 °C is achieved in this way. Alternatively fuel additives have been used that catalytically lower the ignition temperature of the deposited particulate matter. The extra effort involved in handling, storing, and dosing the extra fuel additive onboard the vehicle are obvious. As a further alternative so-called continuously regenerating trap (CRT) systems have been designed. Here the naturally occurring NO is oxidized by a strong oxidation catalyst to NO_2, which is used to continuously oxidize the deposited particulate matter on the filter trap.

7. Conclusion and Outlook

Catalytic exhaust gas treatment is a well-established technology that has allowed a significant reduction of air pollution. Since the first introduction of exhaust catalysts in the 1970s, aftertreatment technology has continuously improved, so that today automotive exhaust catalysis has become one of the most innovative fields of cataytic science and one of the most important applications of heterogeneous catalysis. Today, pollution from vehicles has been reduced by more than 90 % compared to the level before the introduction of catalytic exhaust control. The near future will see even further reductions.

A major remaining challenge for the automotive industry is the lowering of fuel consumption and CO_2 emissions. This is also a challenge for catalyst development, since the most fuel-efficient engines operate with excess air, and the conventional three-way catalyst does not allow NO_x reduction under these conditions. New technologies are being developed that allow fuel-efficient lean operation of the engine and at the same time retain the high emission standards of conventional three-way catalysts.

Early automotive catalysts were more or less add-ons to vehicles. Future emission control technologies will be significantly more complex. One driving force for this increased complexity is the need to apply storage-type catalysts. While conventional catalysts can be operated continuously, storage-type catalysts require cyclic operation with alternating storage and regeneration phases. This unsteady operation requires the catalytic system to be designed as an integral part of the overall fuel- and engine-management system. Consequently, automative emission control has evolved into an interdisciplinary field in which technological and commercial success can only be achieved in an inegrated development process with close cooperation of engine-design engineers, fuel-management experts, and catalysis specialists.

1. History

Turbine-powered aircraft were used by both *British* and *German* air forces for military operations during the latter part of World War II. The British engines were operated on illuminating kerosine containing 1 % light lubricating oil (jet engine oil) [1]. The German engines burned a wider boiling mixture of gasoline and heavier distillate fractions. Fuel development in Germany stopped at war's end. Continuing British research has tightened some requirements over the years, yet today's primary British specifications still describe kerosine-type fuels for both commercial and military aircraft, the main difference being in the additive content.

The initial United States military fuel was a low freezing point kerosine called JP-1, but its limited availability forced the development of a wider boiling fuel that included gasoline as well as kerosine fractions [2]. This "wide-cut" fuel called JP-4 was, until recently, the major military grade. However, safety concerns associated with its flammability led to its phase-out in favor of the kerosine based grade JP-8. The switch from JP-4 to JP-8 was largely completed by the end of 1996.

Commercial aircraft have been burning mostly kerosine-type fuels since 1953 when the early turboprop aircraft came into service, and this has remained the major civil fuel in the turbojets and later the turbofans which power most of the world's civil aircraft fleet. The principal grades are Jet A in the United States, TS-1 in Russia and Jet A-1 in the rest of the world. The wide-cut fuel Jet B, analogous to the military grade JP-4, is now rarely used in civil aviation.

2. Fuel Types and Specifications

The most widely used civil aviation turbine fuel grades are defined by a small number of key specifications as listed in Table 1. These specifications are similar in most respects although a small number of significant differences remain.

Table 1. Major civil jet fuel grades and their specifications

Grade	Area of usage	Major specification
Jet A-1	world-wide	ASTM D1655, DEF STAN 91-91 (DERD 2494)
Jet A	USA only	ASTM D 1655
TS-1	Russia and former Eastern Bloc countries	GOST 10227
Jet Fuel no.3	China	GB 6537
Jet A-1	Canada	CAN/CGSB-3.23

The US Jet A fuel, defined by specification ASTM D1655 [3], differs from Jet A-1 only in freezing point. The British DEF STAN 91-91 specification (formerly well known as DERD 2494 whilst under the jurisdiction of the UK Ministry of Defence) [4] is recognized as a civil jet fuel specification and is used as such in many countries around the world. The Russian GOST 10227 specification also defines a grade designated RT which is very similar to western Jet A-1, as is the Chinese no.3 Jet Fuel.

In addition to these prime specifications, the International Air Transport Association (IATA) maintains fuel "Guidance Material" [5] for Jet A-1 and Jet B grades for the use of its member airlines. Because of the worldwide nature of commercial aviation, the close correspondence between specifications is a necessity to discourage the proliferation of many different national or local specifications. The major jet fuel suppliers subscribe to a document entitled "Aviation Fuel Requirements for Jointly Operated Systems" (AFQRJOS) which defines a "Check List" which comprises the most restrictive requirements of the ASTM D 1655, DEF STAN 91-91 fuel specifications and IATA Guidance Material. Thus fuel meeting the Check List automatically meets all the requirements of the parent specifications. This document was developed to cater for the situation where many different fuel suppliers deliver fuel into the common storage facilities which predominate at most international airports.

Further efforts are underway to minimize the differences between the major fuel specifications with the eventual aim of developing a single, international specification to define aviation turbine fuel. An International Civil Jet Fuel Specification Liaison Group was formed in 1989 to promote this activity and a growing number of national specification bodies are contributing to its progress.

2.1. Specification Requirements

Details of the major fuel specifications for Jet A-1 type fuel are shown in Table 2. Although test methods in most western countries are either identical or very similar, no international standardization exists and direct comparisons between limits may be misleading (refer to the notes applying to Table 2). Test method designations published by the principal standards organizations are given in Table 3.

2.2. Fuel Properties

Unlike most chemicals but like other petroleum fuels, aviation turbine fuels are not defined by composition, molecular structure, and purity. Instead their characteristics are limited by boundary conditions imposed by inspection tests. Some of these tests are fundamental, others empirical; many reflect a solution to past engine or aircraft problems. However, any fuel meeting all requirements is acceptable for aircraft operation. The specifications are dynamic, but changes are conservative because of the potential risk to aviation operations. Long equipment life ($\geqq 20$ years) and certification restrictions (see Chap. 5) also mitigate against drastic specification changes.

The individual specification properties or requirements can be divided rather arbitrarily into bulk and trace properties. *Bulk properties* are those requiring significant composition changes, involving more than 5 vol % of the total fuel, to effect a change in the property. *Trace properties* tend to respond to changes < 1 vol % or even 1 ppm or less. Changes in bulk properties affect product yield, whereas changes in trace properties do not. The grouping has no direct bearing on fuel performance. Instead it helps assess effects of crude composition and manufacturing steps on product yield [8].

2.2.1. Bulk Properties

Density. The mass – volume relationship is important because the quantity of fuel loaded onboard an aircraft is metered volumetrically, but fuel consumption is measured by mass. This relationship is also used extensively in commercial sales of fuel. Although in the past there have been several different ways of defining this relationship, such as specific gravity, relative density, or API gravity, all the major jet fuel specifications now define density at 15 °C in units of kg/m^3. Changes of density with temperature are given in [9]. Density is commonly measured using hydrometers or digital density meters. In-line density measurement is also possible and offers the opportunity for fuel delivery by mass instead of volume.

Specific Energy. Specific energy or heat of combustion is directly related to density. The fuel's specific energy, its density, the aircraft's performance characteristics, and the predicted flight conditions are employed to calculate the amount of fuel required for a given flight or conversely to estimate the aircraft's range with maximum fuel aboard. Specific energy is determined

Table 2. Continued.

[a] Specification limits are in terms of Russian GOST test methods and may not be directly comparable with limits obtained using ASTM test methods.
[b] Specification limits are in terms of Chinese GB/T or SH/T test methods and may not be directly comparable with limits obtained using ASTM test methods.
[c] Value in terms of mg KOH/g calculated from GOST limit which is in terms of mg KOH/100 mL.
[d] 25.0 % max aromatics are permitted provided that hydrogen content is reported also.
[e] NR = no requirement under this heading.
[f] Flash point limits are in terms of ASTM D56 (TAG) test method; limits in parantheses are in terms of other, local, test methods.
[g] The GOST test method records wax appearence point on cooling which is 3 °C below the wax disappearance point on warming, as recorded in the ASTM method. Thus the specification limits for TS-1 and Jet A-1 are equivalent.
[h] It is planned to delete the silver corrosion clasification requirement by June 1997.
[i] If the test at 260 °C produces a failure, a pass at a test temperature of 245 °C is acceptable.
[j] Applies only if fuel produced by copper-sweetening process.
[k] Conductivity limits apply only if fuel contains static dissipator additive.

Table 3. National standard aviation fuel test methods

Test name	ASTM [3]	IP [6]	ISO [7]	GOST [a]

Copper content		225		
Sulfur (Wickbold combustion)		243	4260 : 1987	

[a] Although ASTM, IP and ISO methods are essentially identical, GOST methods may be quite different.

by measuring the total heat released by a unit mass of fuel and subtracting from this value the heat of condensation of the water vapor formed during the combustion. However, this measurement is time consuming, so several empirical relationships have been developed to calculate specific energy from combinations of other inspection tests. The most common is based on the product of aniline point and density, ASTM D 4529 [3]; others use the density, boiling range, and aromatic content, ASTM D 3338 [3], or the hydrogen content and density, IP 355 [6]. All three methods include corrections for fuel sulfur content. Although these calculation methods are used routinely, a method of measurement, ASTM D 4809 [3], is still specified as the referee method for use in cases of dispute.

Volatility. A fuel's volatility or its tendency to vaporize affects evaporation rate from tanks, including aircraft fuel tanks. Volatility can cause vapor lock in fuel systems when the combined fuel and vapor volume exceeds pump capacity; cavitation can result when the fuel vapor pressure exceeds the liquid system pressure between gear teeth or in plain bearings. Volatility also directly affects flammability and causes safety problems both inside and outside of tankage [10]. Because of the complex composition of turbine fuel, its volatility cannot be described by a single fundamental property. Therefore, volatility is normally expressed using a combination of boiling range, flash point, or vapor pressure.

The volatility of kerosine type fuels is controlled by flash point and distillation range (Table 2). Wide-cut fuel is regulated by a combination of distillation range and vapor pressure.

Combustion. Combustion in a modern jet engine is a highly turbulent, high-pressure, and high-intensity mixing process. Engine designers carefully control air flow, fuel flow, and fuel atomization to maximize combustion efficiency and to minimize smoke, carbon deposits, and the formation of partially oxidized gases, such as carbon monoxide. Fuel affects all these as well as the intensity of radiation emitted by the flame [11–13]. No single fuel property requires a greater degree of empiricism than the estimation of fuel combustion characteristics. *Smoke point,* and to a lesser extent the *luminometer,* have been favored because as actual combustion tests, they respond to a combination of other fuel properties including volatility, composition, and viscosity. However, a direct comparison of these laminar, wick-fed flames with the high pressure, turbulent combustor flame is not possible and thus other alternative controls also appear in the specifications. *Naphthalenes content* was added because multi-ring aromatics have shown adverse combustion effects, in terms of flame radiation and smoke formation, out of proportion to their concentration [14]. During the 1980s, the use of hydrogen content, which can be measured very accurately by NMR (ASTM D 3701), gained favor as a possible replacement for the less precise measurements of aromatics and naphthalenes contents. However, it was found that the total hydrogen content of the fuel could not predict reliably the combustion behavior of all fuels[15] and it is now unlikely that it will be adopted for civil fuels, although it continues to find limited use in certain military fuel specifications.

Total aromatic content (ASTM D1319, [3]), covered under "Elastomer Compatibility", does not correlate particularly well with engine combustion, possibly because of the particular separation and classification of hydrocarbons by the method [16].

In general, correlations between engine combustion performance and fuel inspection tests will always be difficult to establish because of the differing performance of the same fuel in different engines, the extreme expense of controlled engine tests, and the long time required to obtain engine experience in the commercial world, where only a limited quantity of minimum quality fuel is burned [16].

Elastomer Compatibility. A major requirement of jet fuels is their compatibility with materials of construction, particularly with the elastomers used in diaphragms, fuel tanks, fuel tank coatings and sealants, linings, and a wide variety of static and dynamic seals in all parts of the fuel system. The fuel property most indicative of elastomer compatibility has been *total aromatic content.*

Low-Temperature Operability. The extremely low temperatures at high altitudes can cause several different fuel problems. During fuel cooling, hydrocarbon molecules precipitate as wax crystals. *n*-Hydrocarbons are the most

insoluble, and in fact measurement of their type and concentration can indicate the insoluble fraction expected at low temperature [17].

The *freezing point* of the fuel is defined as the temperature at which the last wax crystal melts on warming the fuel following a specified cooling process. Traditionally, this has been determined visually but now several automated methods exist which employ variously, light scattering, phase transition measurement or flow through a fine filter (ASTM D 4305) [3].

With the increasing use of twin-engined aircraft on long over-water routes, the so-called extended operations (ETOPS) flights, and with the introduction of very long range aircraft such as the Boeing 747 – 400, there has been increasing focus on fuel low-temperature properties. Studies underway may question the usefulness of "freezing point" as currently measured and could lead to its replacement by a more meaningful, flow-based test.

Low fuel temperature can also affect engine starting, which depends heavily on fuel atomization. Adequate atomization is determined largely by fuel viscosity. Typical viscosities versus temperature are plotted in Figure 1. Because fuels within the same grade have the same viscosity-temperature slope, a single maximum viscosity at a standard temperature adequately controls this property.

Figure 1. Typical viscosities vs. temperature [18]

2.2.2. Trace Properties

Instead of describing trace properties individually, a better overview is obtained by grouping these properties into the following performance categories.

Oxidative Stability. Jet fuel's exposure to oxidative conditions over a wide temperature and time range can result in a wide variety of problems [19].

Ambient temperature oxidation can form peroxides that degrade certain elastomers, e.g. Buna N, which are used in aircraft fuel systems. Long-term storage can cause soluble and insoluble oxidation products labeled "gums". Peroxide formation is usually seen in fuels which have been produced in the refinery by catalytic hydrogen processes (see Chap. 3) which remove certain trace compounds containing sulfur or nitrogen which are natural anti-oxidants. Anti-oxidancy is restored by the addition of oxidation inhibitor additives (Section 3.2). Gum formation is rare but is monitored and controlled by the Existent Gum test.

High-temperature oxidation is of major concern. Oxidation products – gums, lacquers and insoluble deposits – can form in the hot areas of an aircraft's fuel system causing a number of problems[20]. The heat exchanger of the fuel-cooled oil-cooler can lose efficiency; flow control valves in the fuel control unit can stick or jam, coke deposits can form in the burner feed arms which can, in the worst case, cause plugging of the fuel injector nozzles. These deposits represent such a small fraction of the fuel that the oxygen dissolved in the fuel is sufficient to cause their formation. Although deoxygenation is effective on a laboratory scale, in large scale practice it is impossible to reduce the oxygen content of the fuel to a level low enough to prevent oxidation. The problem is attacked by designing aircraft fuel systems to minimize hot spots; indeed, thermal management is one of the most important criteria in modern engine and aircraft design. In addition, the thermal stability of fuel supplies is controlled by a test in the fuel specification (Table 2) using an instrument called the Jet Fuel Thermal Oxidation Tester (JFTOT), which is a small-scale simulation of a heat exchanger in which formation of lacquer and deposit are measured (ASTM D 3241) [3].

Certain metals, notably copper, are oxidation catalysts and when dissolved in the fuel at extremely low levels, e.g. 20 µg/kg (ppb), can promote thermal instability and deposit formation. Traces of copper can be picked up by the fuel from copper-containing alloys sometimes encountered in the refinery or during transportation. The deleterious effects of this dissolved copper can be alleviated by dosing the fuel with a metal deactivator additive (Section 3.2).

Corrosivity. Corrosion of fuel system metals can be a problem. Copper or bronze in early fuel pump bearings and other components needed protection [1]. Silver surfaces in highly loaded portions of variable displacement pumps were attacked and ultimately removed by shear forces [21]. *Dihydrogen sulfide* and elemental *sulfur* were identified as culprits. As little as 0.5 mg/kg (ppm) of either material caused the difficulties. As a result, all the major fuel specifications contain a test for copper corrosion. The DEF STAN 91-91 (DERD 2494) specification has, in addition, a test for silver corrosion

Solutions to other corrosion difficulties have addressed the offending fuel constituent rather than the metal involved. *Thiols* cause cadmium corrosion [1] and are limited in fuel specifications. *Sulfur,* which includes all organosulfur compounds, causes high-temperature turbine blade corrosion, particularly in the presence of sodium [22]. However, such low sulfur concentrations cause corrosion that virtually complete sulfur removal from the fuel would be needed to solve the problem, and blade metallurgy was changed instead. Therefore the current sulfur specification maxima are not based on any corrosion criteria.

Organic acidity, primarily as naphthenic acids, has been blamed for some diesel engine corrosion, but the low-acidity level permitted by the jet fuel specifications appears to have prevented similar aviation difficulties. The primary role of organic acids is their involvement in the formation of surface-active agents as discussed in the next paragraph.

Water Separation. Free or immiscible *water* is a potential major hazard in aircraft. When cooled below 0 °C the resulting ice can block orifices, screens, or filters. In large quantities water will "put out the fire" by interrupting fuel flow. Water can lead to microbial growth in stagnant parts of the fuel system. Therefore, every effort is made to remove all immiscible water by special filter-separators before the aircraft is fueled. Satisfactory operation of these filters depends on the maintenance of internal hydrophobic surfaces. Trace levels of surfactants render these surfaces ineffective [23]. Although the organic acids normally in jet fuel are not strong surfactants, they react with sodium hydroxide or other basic materials. The resultant salts or soaps can have detrimental effects [1], [24], [25]. The lower organic acidity maximum in the British specification offers greater protection in this regard than does the higher level in ASTM D 1655, but surfactants are not limited to those formed by organic acids, and additional tests are used for surfactant detection and control.

The Water Reaction test gives a semiquantitative indication of insoluble interface material formed when fuel is shaken with buffered water. In a much more sensitive test a fuel–water emulsion is pumped through two layers of coated fiberglass from a filter-separator. The ability of the filter element to strip all water from the emulsion is measured.

The earliest test, the Separometer (ASTM D 2550 [3]), was developed to detect low levels of sodium sulfonate [33]; but this test as well as the later versions, the Miniseparometer (ASTM D 3602) and the Microseparometer (ASTM D 3948), are widely used in the United States and elsewhere to test for the presence of various surfactants. Because of the difficulties in correlating results from these tests with field performance, there is only limited industry agreement on the definition of acceptable fuel by these tests. ASTM D 2550 and D 3602 have now been discontinued.

Static Electricity. Whenever a hydrocarbon liquid flows with respect to another surface, an electrical charge is generated in the liquid and an equal but opposite charge is imposed on that surface. One set of charges is swept along with the fuel while the opposite charges, which accumulate along the wall surface, usually leak to ground (earth). This charge separation results in a rise in voltage in the moving fuel [26]. High speed pumping of aviation fuel through pipes and filters can generate very high charges and when the charged fuel enters a tank, a substan-

tial voltage difference may be produced between the surface of the liquid and the tank walls and this may result in a static discharge [27]. If the vapor space above the liquid is in the flammable range, such a spark discharge can cause a fire or explosion.

Charge build-up can be reduced by reducing the flow-rates of the fuel or designing and constructing facilities – pipework, filters, valves, etc. – to minimize charge generation and/or provide time for the charge to relax to ground before entering a tank [28]. Another approach is to add a static dissipater additive to the fuel (Section 3.2) to increase the electrical conductivity of the fuel to facilitate charge relaxation.

2.3. Nonspecification Properties

Some aviation fuel properties are not limited by specifications but are useful in equipment design or performance.

Absolute Vapor Pressure. Reid vapor pressure, specified for Jet B fuel, is not an absolute vapor pressure because it is measured with a vapor–liquid ratio of 10 : 1; it is determined only at 38.8 °C, and also it includes the partial pressures of water vapor and air. With low-vapor-pressure products, such as Jet A or A-1, absolute or true vapor pressure is used instead. Figure 2 shows typical true vapor pressure-temperature curves for different jet fuel grades [18].

Figure 2. True vapor pressures [18]

Water Miscibility. Even the very low concentration of dissolved water in aviation turbine fuels is hazardous if this water separates and freezes in a critical aircraft location. Because dissolved water cannot be avoided in vented systems and is not removed by airport fuel handling equipment, aircraft fuel systems either heat the fuel above 0 °C or depend on anti-icing additives (see Section 3.2). Typical water saturation levels for commercial jet fuels are listed in Table 4 [18].

Table 4. Typical nonspecification properties [18]

	20 °C	40 °C	60 °C
Water solubility, vol %			
Jet A, A-1	0.0049	0.0088	0.0163
Jet B	0.0076	0.0138	0.0255
Specific heat, kJ kg^{-1} K^{-1}			
Jet A, A-1	1.95	2.04	2.13
Jet B	2.06	2.14	2.23
Thermal conductivity, Wm^{-1} K^{-1}			
Jet A, A-1	0.1155	0.1124	0.1085
Jet B	0.1155	0.1124	0.1085
Dielectric constant at 400 Hz			
Jet A, A-1	2.13	2.10	2.07
Jet B	2.06	2.03	2.00
Surface tension, mN/m			
Jet A, A-1	23.3	21.7	20.2
Jet B	21.8	20.5	18.4

Lubricity. Various aircraft fuel system components – fuel pumps, servo valves, fuel control units – rely on the fuel to lubricate their moving parts. The effectiveness of a jet fuel as a lubricant in such equipment is referred to as its "lubricity". Differences in component design and materials result in varying degrees of equipment sensitivity to fuel lubricity. Similarly, jet fuels vary in their level of lubricity. The chemical and physical properties of jet fuel cause it to be a relatively poor lubricating material under high temperature and load conditions where lubrication may depend on adsorbed films of trace polar compounds present in the fuel, so-called "boundary lubrication". Severe hydroprocessing (see Chap. 3) removes trace components, resulting in fuels which tend to have lower lubricity than straight-run or wet-treated fuels. This lack of lubricity can be remediated by the addition of corrosion inhibitor/lubricity improver additives (Section 3.2). Such additives are mandatory in most military jet fuel specifications but they have not found widespread use in civil aviation. It is generally acknowledged that the ultimate solution to the fuel lubricity "problem" is to design fuel system equipment such that it is insensitive to fuel lubricity. Civil fuel specifications do not contain a requirement for a minimum level of lubricity, not least because there is no method of test for this property which is universally accepted. One method, the Ball-on-Cylinder Lubricity Evaluator (BOCLE) ASTM D 5001 [3], can be used for identifying possible problem fuels and is used by equipment manufacturers to monitor special low-lubricity fluids used in development testing of fuel system equipment, and by the USAF to monitor the lubricity additive concentration in their fuel supplies.

Other Properties. Detailed data on other properties, including gas solubility, flammability, surface tension, heat of vaporization, enthalpy, specific heat, thermal conductivity, and dielectric constant, are contained in the *CRC Handbook of Aviation Fuel Properties* [18]. Some typical values for several properties are given in Table 4.

3. Production

3.1. Fuel

Since its earliest days virtually all aviation turbine fuel has been refined from selected petroleum crudes by atmospheric distillation followed by limited processing to reduce thiol or total sulfur. Crude selection is vital for such simple processing because the only other variable available for controlling bulk properties is adjusting the product's *boiling range*. Desirable crudes are low in sulfur (sweet crudes), low in *n*-hydrocarbons (nonwaxy crudes), low in aromatic content, and high in product boiling between 160 and 290 °C.

Adjusting either end of the boiling range has predictable results. Lowering the initial boiling point improves combustion and low-temperature properties but decreases handling safety (see Table 5). Raising the final boiling point degrades combustion and low-temperature performance and has no effect on handling safety. Because the crude also yields both lighter and heavier fractions, the demand for these products affects distillation cut points and therefore the volume of jet fuel available [29].

Table 5. Alteration of boiling range

Lowering initial temperature	Raising final temperature
Increases	
smoke point	density
hydrogen content	aromatic content
J/mass	naphthalenes
vapor pressure	viscosity
Decreases	
density	smoke point
flash point	hydrogen content
aromatic content	J/mass
naphthalenes	
freezing point	
J/vol	
viscosity	
Leads to	
better combustion quality	poorer combustion quality
better low-temperature properties	poorer low-temperature properties
poorer handling safety	unchanged handling safety
higher gravimetric specific energy	lower gravimetric specific energy
lower volumetric specific energy	higher volumetric specific energy

Total sulfur can be reduced by relatively low-pressure hydrotreating. Thiol sulfur is reduced

(sweetened) by low-pressure hydrotreating or wet chemical treating, such as Merox, Linde, Doctor, or Bender treating. Flash point may be adjusted so that the same product can be sold as either aviation turbine fuel or commercial illuminating or heating kerosine.

Some heavier fractions are hydrocracked to make jet fuel, but the 160 – 290 °C fraction from catalytic cracking is not suitable for jet fuel unless cracking is followed by high-pressure hydrotreating. A limited amount of kerosine is hydrotreated to reduce aromatic content and increase smoke point by aromatic saturation. In the United States the finished jet fuel is often filtered through towers of activated Attapulgus clay to adsorb surfactants and to remove particulate fines.

3.2. Additives

All aviation fuel additives must be tested and approved. The extent of testing is at the discretion of the aircraft and engine manufacturers who issue the approval. Additive composition plays a major part in approval procedures, with ash-forming materials receiving the greatest scrutiny. Recommended Practice D 4054 (ASTM) [3] covers the evaluation of compatibility between additives and aircraft fuel system materials. Approved additives and their permitted levels are normally listed in the fuel specifications. Unapproved additives cannot legally be used in aircraft operation.

Oxidation Inhibitors. Oxidation inhibitors prevent peroxide formation and improve storage stability in certain fuels (→ Antioxidants). They are generally secondary and tertiary hindered phenols and are listed in the fuel specification by chemical composition. They are effective primarily during storage, not during high-temperature use. Antioxidants are mandatory for hydroprocessed fuels in the major military fuel specifications and in civil Jet A-1 covered by the DEF STAN 91-91 (DERD 2494) specification and IATA and Joint System Checklist documents, but only optional in the ASTM D 1655 specification. Dosage rate is 17 – 24 mg/L. Annual consumption of oxidation inhibitors in aviation turbine fuel is difficult to estimate because the same additives are widely used in other petroleum products.

Metal Deactivators. Metal deactivators are intended to passivate trace metals by chelation (→ Antioxidants). The only approved deactivator is *N,N′*-disalicylidene-1,2-diaminopropane [*94-91-7*]. It is permitted up to 5.7 mg/L, but is rarely used.

Corrosion Inhibitors and Lubricity Improvers. Unlike the preceding additives, corrosion inhibitor formulations are proprietary. They usually contain dibasic acids that function as liquid phase rust inhibitors. The polar ends of the molecule adsorb onto metal surfaces and in ground handling and distribution systems, e.g., steel pipelines, they act to protect surfaces from corrosion. In aircraft fuel systems, the tendency to adsorb on to metal surfaces is utilized for lubricity improvement rather than corrosion inhibition. Because these additives are surface-active (commonly referred to as "surfactant"), they can display the adverse side-effect of impairing the water separation properties of the fuel. Furthermore, their surfactancy means that they can be lost from the fuel during distribution (as, of course, they should be if they are to protect metal surfaces from corrosion); consequently, if added for lubricity enhancement, these additives are often injected at the airport, just prior to aircraft fueling. Lists of approved additives are published in the Qualified Products Lists (QPLs) associated with the U.S. MIL-I-25017 and UK DEF STAN 68-251 specifications for this type of additive.

Static Dissipater Additives (SDAs), also referred to as Conductivity Improving Additives, are added to jet fuel to increase electrical conductivity, and thereby reduce the tendency of a fuel to accumulate dangerous electrostatic charge during handling [28]. There are only two additives approved for use in aviation fuel, Shell ASA-3 and Octel (formerly Du Pont) Stadis 450. Production of the Shell additive ceased in 1991 leaving Stadis 450 as the only additive currently available. The concentration is adjusted to obtain an electrical conductivity within the range 50 – 450 pS/m but with a maximum permitted dosage of 3 mg/L. A further addition up to 2 mg/L is permitted if conductivity has been

lost during fuel distribution. The minimum conductivity limit is set to ensure charge relaxation sufficient to alleviate static discharges, while a maximum limit is applied to avoid causing anomalies in aircraft fuel tank contents gauges which operate on an electrical capacitance principle. The use of SDA is mandatory in military JP-4 and JP-8 fuels and in civil Jet A-1 outside the United States ; its use is optional in Jet A fuel within the United States.

Anti-icing additive, also referred to as Fuel System Icing Inhibitor (FSII), prevents the freezing of trace levels of free water in fuel at the low temperatures encountered in aircraft fuel tanks at high altitudes and avoids blockage of fuel lines and filters by ice crystals.). Traditionally, ethylene glycol monomethyl ether (2-methoxyethanol) [*109-86-4*] , has been used for thispurpose but, owing to its toxicity, this has largely been superseded by diethylene glycol monomethyl ether (2-(2-methoxy)ethanol) [*111-77-3*]. Normal dosage rate is between 0.1 – 0.15 vol %.Such use is mandated in military fuels but in civil aviation its use is restricted to small aircraft which do not have heaters in their fuel systems. The additive, which is only sparingly soluble in the fuel, preferentially dissolves in any free water present (partition coefficient about 200 : 1) where it acts as an antifreeze (→ Antifreezes). This affinity for water can be problematic in fuel distribution systems and additive loss must be considered and possibly corrected. FSII has the additional property of acting as a biostat, preventing the growth of bacteria and fungi in fuel tanks (see below).

Biocides. Microorganisms that metabolize hydrocarbons can be present in both ground and aircraft fuel systems [1]. Certain anaerobic bacteria that reduce sulfate to hydrogen sulfide have caused copper and silver corrosion. The formation of slimes, fungal mats, and corrosive byproducts has caused wing tank corrosion and capacitance gage failures. The only generally approved fuel-soluble biocide is Biobor JF (Hammonds), a blend of 95 % dioxaborinanes and 5 % naphtha. Recommended dosage to kill microorganisms is 226 mg/L; maintenance level is 108 mg/L. An alternative material, which is approved for most applications, is Kathon FP1.5 (Rohm & Haas) which is based on a mixture of a methyl-isothiazolinone [*2682-20-4*] and a chloromethyl isothiazolinone [*26172-55-4*].Treatment levels are between 100 and 300 mg/L. Although treatment withbiocides kills the microbial growths in fuel tanks, subsequent tank cleaning is still essential to remove all the dead material which might otherwise lead to filter blockage.

Thermal Stability Additives. In the early 1990s, the USAF perceived that future aircraft designs would demand a fuel with enhanced thermal oxidative stability. They decided that the most economic way of achieving this would be to use fuel additives to increase the thermal stability of the existing fuel type, JP-8, rather than developing a special fuel. It was calculated that an increase of 100 °F (56 °C) in the thermal stability level of the fuel would be required and this led to the new fuel being referred to as "JP-8 + 100". The extensive research program to develop and test such additives was referred to as "HiTTS", standing for High Temperature Thermal Stability [30]. The main problems at high temperature are fouling of the injector feed arm and coking in the fuel supply rings to the augmenter (afterburner or reheat) section. An additive package comprising a detergent/dispersant, an antioxidant, and metal deactivator proved to be very effective in preventing deposit formation in the hot areas of existing aircraft fuel systems. Already the benefits in terms of reduced maintenance costs are being appreciated. However, because the dispersant/detergent element of the additive package is very surface active, it cannot be added to the fuel in storage because it would encourage water and dirt pick-up and also disarm the filter/water separators in the airport fueling system. Instead, the additive package is injected into the fuel as the aircraft is being fueled.

4. Handling, Storage, and Transportation

System Descriptions. It is essential to prevent aviation fuel from being contaminated with other petroleum products between the time it is manufactured in the refinery until the moment it is put on-board an aircraft. Consequently

fixed storage facilities are designed to keep aviation fuel physically isolated from other products. However, large pipelines, marine transports and sometimes even road tankers are multiproduct systems. Each transportation mode therefore has an elaborate protocol to protect the quality of all the products it carries. Pipelines carry compatible products both preceding and following jet fuel; the interface between products is cut into the non-aviation grade. Marine and road transports depend on cleaning procedures, with the amount and type of cleaning dependent on the preceding product. When aviation fuel has been transported through a non-dedicated (i.e., a multiproduct) system, samples are taken for recertification testing in which those properties most sensitive to contamination, e.g., flash point, freezing point, gum, etc., are retested and the results compared with the original values reported on the refinery Certificate of Quality to confirm that no inter-product contamination has occurred. At the airport, the fuel is delivered from storage to the aircraft either via underground pressurized piping (hydrant system) through mobile hydrant dispensers or by specialized tank trucks called fuelers. Both types of fueling vehicle are equipped with filter/water separators or filter monitors to ensure only clean, dry fuel is pumped into the aircraft.

Contamination Removal Equipment. Multiproduct transportation systems and long distances between refinery and airport furnish opportunities for water, rust, dust, surfactants, and other contaminants to enter the fuel. Specialized equipment and procedures remove these unwanted materials [31]. Water and solids settle in storage, assisted by suction lines that float just beneath the liquid level. Filter/water separators [32] and filter monitors [33] remove free water and fine solids, while activated Attapulgus clay filters can be used to adsorb surfactants.

The operation of this equipment is checked regularly with a variety of test equipment. Solids are detected and measured per ASTM D 2276 and ASTM D 3830 [3]. Surfactant removal by clay filters can be observed with the Microseparometer (ASTM D 3948 [3]). A variety of tests exist for the detection of low levels of undissolved or free water, with most of the tests containing a water-sensitive dye; ASTM D 3240 [3] measures water levels ≥ 1 ppm.

5. Legal Aspects

All aircraft, including all flight components, are certified for flight by a government agency which promulgates and enforces the certification rules. These rules have the force of law. Aircraft and engines use fuel meeting certain specifications during certification. These specifications become part of the aircraft's operating certificate. The fuel must therefore completely meet the certification specification even though a deviation may not affect operation adversely. Normally aircraft and engine manufacturers designate industry fuel specifications (e.g., ASTM D 1655 [3]), but manufacturers can certify to their own proprietary specification. In such a case any points of difference from the industry norms must be specified. Once certified, aircraft must be operated by the rules of the country in which they are registered.

6. Environmental Aspects

Aircraft exhaust emissions are controlled by regulations issued by the International Civil Aviation Organisation (ICAO). These regulations define the permitted levels of emissions of nitrogen oxides (NO_x), carbon monoxide, unburned hydrocarbons, and smoke for each engine type. At present, emissions are controlled only for the landing/take-off (LTO) cycle, which is defined as engine idle, taxi out, take-off, and climb to 900 m, descent from 900 m, taxi in, and idle. Exhaust emissions at altitude are not restricted although there are numerous studies underway to determine the effects of high altitude emissions on global warming and ozone depletion [34–36]. Future regulation is expected but this is likely to be met by further advances in combustion chamber design rather than from significant changes in the composition or properties of aviation fuel.

7. Economic Aspects

Compared with gasoline and diesel fuel production, aviation turbine fuel represents a small proportion of the crude barrel. In 1995, worldwide

production of kerosine was 285×10^6 t of which ca.190×10^6 t was for jet fuel with the remainder for non-aviation uses (heating, lighting, cooking, etc.). This total kerosine volume represents ca. 9 % of world oil consumption [37]. World air travel is predicted to grow, on average, by 5.5 % per year over the next decade and 4.9 % over the coming twenty years [38–40]. Highest growth rates are in the "Pacific Rim" countries. By 2006, air travel will rise by nearly 75 %; by 2016, it will reach two-and-a-half times current levels. Fuel volumes will also grow significantly but at a lower rate due to improvements in aircraft fuel efficiency. The United States is the largest single consumer of jet fuel with about 50 % of the total world volume; this share is expected to decrease in the future as the Far Eastern economies continue to grow.

A forecast of world aviation fuel demand in 10^6 t is given below [37]:

1990	1993	1995	2000	2005	2010	2014
161	175	189	255	330	420	500

8. Future Trends

8.1. Petroleum-Derived Fuels

Despite the predicted increase in demand for aviation fuel, there should be no overall supply problem. Both refining capacity and processing technology are available to supply these volumes. Whether the quality of jet fuel will change significantly in the future is open to debate. In the early 1980s, predictions tended to be gloomy with the expectation that fuel quality would inevitably deteriorate due to decreasing availability of sweet crudes and the increasing use of heavy and high sulfur crudes. This led to design studies aimed at developing engines which could cope with the resultant poorer combustion quality [41]. However, these predictions were not borne out during the 1980s and 1990s because new oilfields continued to be discovered. Advances in process technology will be able to maintain, or even improve on, fuel quality for the foreseeable future.

Conventional petroleum crude will continue to form the major source for jet fuel production well into the next century. Experimental production of jet fuel from oil shale in the United States during the 1980s, although successful, was terminated because it was economically non-viable in a world of continuing low crude oil prices. However, this technology remains on the shelf and could be resurrected should the economic climate change significantly. Production of jet fuel from tar sand derived crudes is practiced in Canada, but gives only a very small proportion of the total fuel production.

Synthesis of liquid fuels from natural gas can be achieved by the Shell Middle Distillate Synthesis process (SMDS) [42], [43]. Whilst producing kerosine of a very high quality in terms of combustion performance, the SMDS product itself is unlikely to be suitable as a jet fuel because its complete lack of aromatics causes concern in the areas of compatibility with elastomers and lubricity. However, the product remains an excellent blending component for upgrading lower quality conventional kerosines which would otherwise be unsuitable as jet fuel

8.2. Alternative Fuels

Kerosines derived from *coal* using the Fischer–Tropsch process (→ Coal Liquefaction, Chap. 2.2.) have been synthesized in South Africa by SASOL for a number of years. The process produces kerosine which could be considered suitable as jet fuel although it has never been supplied as such. Although energy intensive, increasing jet fuel demand in southern Africa has prompted the producers of this synthetic product to seek approval from the aircraft and engine manufacturers for its use as jet fuel. However, like SMDS kerosine, many of the coal-derived fractions contain no aromatics and will need to be blended with other streams before being acceptable. Although this production route has been confined to South Africa, at some time in the future it may be applied in other countries with large coal reserves, e.g., China. *Oxygenated liquids* like alcohols or esters have been examined as potential aviation fuels or fuel constituents. The pure materials penalize aircraft operation by their much lower specific energy content, whereas blends with petroleum fuels may suffer from water extractability and system material compatibility difficulties [29].

Thus the widespread adoption of oxygenated compounds, particularly methanol, as commercial aviation fuel appears unlikely.

It is often said that the long-term future may lie with *cryogenic fuels* such as liquid methane or liquid hydrogen. Successful flights have been made using methane in Russia, while the "Cryoplane" project [44] is aimed at proving the feasibility of a liquid-hydrogen powered aircraft. However, a major barrier to these cryogenic fuels is that they cannot be used in conventional aircraft, and a new generation of aircraft specifically designed for them would need to be developed. Furthermore, completely new production, storage, distribution, and handling systems would have to be constructed all around the world to ensure supply at all major airports. Proponents of cryogenic fuels tend to underestimate the capital investment involved in establishing a supply infrastructure and it is questionable whether these fuels will ever become commercially viable [45]. *Methane* may be more advantageously used as the starting material in the manufacture of conventional liquid hydrocarbon fuels rather than as a liquid fuel itself [46]. *Liquid hydrogen* has excellent combustion qualities and produces no CO_2 and, at first sight, appears to be more environmentally friendly than conventional kerosine-based jet fuel. However, unless it is produced via nuclear or hydroelectric power, its production from petroleum resources would continue to consume energy and produce CO_2. Moreover, combustion of hydrogen in aircraft engines would still not avoid the production of NO_x and, furthermore, produces 2.5 times as much water vapor as kerosine, which will also contribute to the greenhouse effect.

The massive investments required for new fuels together with the long lead time in design and certification will encourage the use of fuels similar to those currently used for the longest possible time.

1. Introduction

The azine dyes include the phenazine, the oxazine, and the thiazine dyes. They correspond to the following general formula, the most important resonance formulas of which are shown:

In these formulas D^1 and D^2 stand for an auxochrome group, usually an amino, arylamino, monoalkylamino, dialkylamino, or hydroxyl group; X stands for −O−, −S−, or −NR− (R = H, alkyl, aryl); and n is 0 or 1. Therefore, resonance formula **1** only has meaning when $n = 1$. The azine dyes include cationic, anionic, and neutral dyes, depending on the kinds of auxochrome groups and substituents. The multitude of possible resonance formulas is responsible for the deep and intense color of the azine dyes. The azine dyes have this in common with the methine dyes and the triphenylmethane dyes, and they all obey the same general theory of methine dyes [1].

Monoamino- and diamino-, monohydroxy- and dihydroxy-, and aminohydroxyazine dyes are differentiated according to the kind and number of auxochrome groups in formulas **1** – **1**. Because hydroxyazine dyes are present predominantly in the keto form (D^1 or D^2 is =O), they are referred to as phenazone, phenoxazone, and phenothiazone dyes.

It is clear from the general formulas above that, because of the −X− moiety, azine dyes are cyclized derivatives of indamine or indophenol dyes. This relationship is not only of a formal nature; the most important methods of preparation of the phenazine, oxazine, and thiazine dyes proceed via an intermediate indamine or indophenol dye. Either one component of these intermediates already contains the −XH group, and ring closure can take place immediately, or

© 2005 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a03_213.pub2

the −XH group must first be introduced into the indamine or indophenol dye in a separate step. Oxazine dyes are prepared by the former procedure, thiazine dyes by the latter, and phenazine dyes by both.

Loveless, Brown, and Horrocks [2] investigated spectrophotometrically the formation of the phenazine ring via cyclization of *N*-(2-aminophenyl)-*p*-benzoquinonediimine **2**, the oxidation product of 2,4′-diaminodiphenylamine **2**. In the pH range 6 – 9, the amino group adds intramolecularly to the quinone ring, and 2-aminophenazine **2** is formed by oxidation. Above pH 10, hydrolysis of the imino group occurs, and *N*-(2-aminophenyl)-*p*-benzoquinoneimine **2** is formed. In this case, too, the amino group adds to the quinone ring, and 2-hydroxyphenazine **2** is obtained by oxidation.

In an investigation of the reaction kinetics, Corbett [3] was able to establish the following mechanism of formation of phenosafranine **3** by the joint oxidation of *p*-phenylenediamine and aniline (see top of next page).

A rapid oxidation reaction is followed each time by the rate-determining nucleophilic addition of aniline to the quinoid system. The final addition step takes place intramolecularly, forming the phenazine ring system. In a similar system, the formation of indophenols in the Gibbs reaction, the initial step is a single electron transfer reaction between the quinoid system and the phenolate anion followed by fast combination of the radicals or by a chain reaction sequence [4].

A further method for preparation of phenazine dyes involves the reaction of azo compounds with aromatic amines. In this case, the formation of the indamine is preceded by a series of oxidation, reduction, and disproportionation reactions [5]. The first step is the exchange of the 1-amino group of 1-amino-4-benzeneazonaphthalene for the aniline moiety yielding **4**. Subsequently, an autocatalytic reaction begins according to the scheme on the bottom of the next page.

Common to both reaction mechanisms is the fact that two indamine intermediates (**3** and **3**, and **4** and **4**, respectively) precede the formation of the phenazine dyes **3** and **4**.

The ring-forming sulfur atom in the thiazine dyes is also introduced by addition to a quinoid intermediate. In addition to hydrogen sulfide and sulfides, sodium thiosulfate is used as sulfur donor in the most important industrial preparation procedure [6]; thiosulfonic acids are formed

as intermediates, which are cyclized via the indamine **5** to the thiazine dye **5**. This reaction sequence was elucidated as early as 1885 by BERNTHSEN for Methylene Blue.

In the preparation procedures discussed so far, the indamine dye that is required as intermediate is always prepared by oxidation of 1,4-diamines. It can also be obtained by the condensation of nitroso derivatives of aromatic amines in acidic alcoholic solution. The reaction is especially used for the preparation of oxazine dyes. 3-Hydroxyanilines are used as aromatic amines that contain the ring-closing oxygen atom [7]. When the nitroso compound contains an alkoxyl group, cyclization can also take place with elimination of alcohol. This is the case for Basic Pure Blue G **6** [8], which is especially important industrially.

16

Azine dyes with hydroxyl groups as auxochromes are prepared analogously by cyclization of indophenols **7**, which are obtained by the action of aromatic amines on aromatic hydroxy compounds:

17

In dyes that contain only one auxochrome group, i.e., in which $n = 0$ in the general formula **1**, a second auxochrome group D^2 can be introduced if, instead of this group, a nucleophilically replaceable group is present, e.g., the sulfo group [9]:

In the absence of such a leaving group, the introduction of the auxochromic group is carried out successfully by the use of oxidizing agents. Starting from phenazinium salts monoaminophenazine dyes [10] and even diaminophenazine dyes can be obtained in a similar way [11]:

Starting from 10*H*-phenothiazine two (substituted) anilino groups can be introduced as auxochromes by using iodine as oxidizing agent yielding 3,7-bis(arylamino)phenothiazine dyes [12].

History. The oldest synthetic organic dyes belong to the group of azine dyes. In 1834, Runge found that aniline salt yielded dark green pigments on oxidation with dichromate or other oxidizing agents. Lightfood studied the oxidation of aniline in the presence of copper salt as oxygen-transfer agent and thus found in 1863 the first industrially useful procedure for the preparation of Aniline Black [*13007-86-8*].

In 1856, Perkin discovered mauveine **10** [13], which imparted to silk violet hues having a beauty so far unknown; it was also used to print postage stamps:

mixture with R = H, CH_3 **18**

The discovery of the induline dyes by Caro and Dale followed in 1863, and the discovery of the nigrosines by Coupier in 1867. Both groups of dyes represent extremely complex structural mixtures of phenazine dyes.

The first thiazine dye, named after its discoverer, was Lauth's Violet [*581-64-6*], which was obtained in 1876 by joint oxidation of 1,4-phenylenediamine and hydrogen sulfide with iron(III) chloride. However, the dye class achieved industrial importance only when CARO discovered Methylene Blue that same year at BASF.

Meldola's Blue [*7057-57-0*], the condensation product of nitrosodimethylaniline and 2-naphthol, was described in 1879; it is the oldest industrially produced oxazine dye. In 1928, Kränzlein, Greune, and Thiele discovered the group of dioxazine dyes by reaction of aromatic amines with chloranil followed by cyclization, the triphendioxazine base structure itself being known since 1890.

2. Phenazine Dyes

The basic aminophenazine dyes are suitable for dyeing wool, silk, and leather directly, and cotton mordanted with tannin or Katanol. They are only still of importance as leather dyes or for the dyeing of paper pulp. The basic aminophenazine dyes also include the nigrosine and the induline bases. The former are still widely used today to color phenolic resin moldings, typewriter ribbons, shoe polishes, and printing inks, as well as for the spin dyeing of polyacrylonitrile fibers.

The dyes that contain sulfo groups exhaust from neutral or acidic bath onto wool. They level satisfactorily; some are distinguished by good fastness to washing and to fulling and by adequate fastness to light. The acidic nigrosine and induline dyes are suitable for the dyeing of paper and leather.

The oxidation dyes are also classed with the phenazine dyes. They are formed when aromatic mono- and diamines applied to human hair or animal hairs or to cotton or synthetic fibers are treated with oxidizing agents.

2.1. Monoaminophenazine Dyes

Dyes that contain a naphthalene ring system are industrially useful. *Rosinduline dyes* bear the amino group on the naphtho ring, *isorosinduline dyes* on the benzo ring. Basic isorosinduline dyes, which are obtained by reaction of the nitroso derivatives of tertiary aromatic amines with *N*-alkyl- or *N*-aryl-2-naphthylamines, are suitable for the dyeing and printing of textiles containing acid groups. The dye **11**, obtained by heating 4-nitrosodiphenylamine and *N*-phenyl-2-naphthylamine in alcoholic hydrochloric acid, dyes polyacrylonitrile navy blue [14]. It can be used as a color base [15] or as a salt [16] for the spin dyeing of polymers or mixed polymers of acrylonitrile.

19

Basic rosindulines are proposed for the batch dyeing of polyester materials [17].

Induline Scarlet **12**, C.I. 50 080 [*2611-49-6*] (BASF, 1892), is prepared by heating 1-aminonaphthalene in phenol with the azo dye obtained from aniline and *N*-ethyl-*p*-toluidine [18].

20

Acid rosinduline dyes are prepared by the action of oleum or chlorosulfonic acid on the color bases, e.g., *Azocarmin BX*, C.I. 50 090.

Acylated leuco derivatives of monoaminophenazine dyes are recommended as magenta developing components in photothermographic dry silver materials [10].

Acetone can be condensed with two equivalents of 2-amino-4-chlorodiphenylamine under oxidative conditions. Subsequent quaternization leads to **13**, which dyes polyacrylonitrile in a brilliant orange shade [19]:

21

2.2. Diaminophenazine Dyes

The *eurhodines* and the *safranines* belong to the class of diaminophenazine dyes. The eurhodines bear a hydrogen atom or an alkyl group on the azine nitrogen atom; the safranines bear a phenyl group, which can be further substituted if necessary. If a naphthalene ring system is fused to the azine ring, the dyes are called benzophenylsafranines or, if naphthalene rings are fused to both sides, dibenzophenylsafranines. *Indulines* and *nigrosines* bear, in addition to the auxochrome groups, further phenylamino groups.

2.2.1. Eurhodine Dyes

Neutral Violet (**14**, R = H), C.I. 50 030 [*167382-91-4*], and *Neutral Red* (**14**, R = CH_3, *Toluene Red*), C.I. 50 040 [*553-24-2*] (Cassella), are seldom used these days. They are obtained by condensation of 4-nitrosodimethylaniline with 1,3-diaminobenzene or 1,3-diamino-4-methylbenzene [20].

22

The formation of aggregates was investigated for Neutral Red [21]. The dye can be used for the detection of cells with phagocytic activity [22]. Dyes that bear β-chlorethyl groups instead of methyl groups have antitumor activity [23].

By reaction of Neutral Red with epichlorhydrin, the hydrogen atoms of the amino group are replaced by 2-hydroxy-3-chloropropyl groups. This compound dyes wool, polyamide, and cellulose, covalent bonds being formed [24]. In contrast, methyl halides alkylate the azine nitrogen atom and yield a dye which has improved fastness to alkali.

Dyes with additional alkyl-substituted amino groups in positions 2 and 8 show a significant bathochromic shift like indulines (see Section 2.2.4), but in contrast thereto exhibit high fluorescence and singlet oxygen quantum yields [25].

Dyes of the Neutral Red type, as well as basic safranine dyes, are suitable for fast dyeing of polyolefin materials in red, violet, and blue tints [26]. They can be used for dyeing human hair [27].

Acylated leuco derivatives of Neutral Red are disclosed for use in electrochromic recording materials [28].

2.2.2. Basic Safranine Dyes

Safranine T extra **15**, C.I. 50 240 [*477-73-6*], is offered for the dyeing of leather. Preparation

starts with the reduction of aminoazotoluene to give an equimolar mixture of 2-toluidine and 2-methyl-1,4-phenylenediamine, and is followed by oxidation in the presence of added aniline to give the azine dye.

23

By the action of nitrite, it is converted to a blue diazonium salt, which on heating forms the 3,7-dihydroxy compound [29]. Safranine T can be used to remove lignin from mechanical wood pulp [30]. The dye is disclosed as colored charge-controlling agent in toners for electrophotography [31] and as photosensitizer in solar cells [32]. Safranine dyes are also suitable for use in photoelectric processes [33]. Furthermore, they can be used as desensitizers in direct-positive printing-out emulsions [34], for photopolymerization using visible light [35], as light filters with variable optical density [36], and as dye components in soluble complex-forming molecules used in affinity-specific separation of nucleic acids [37]. Safranine dyes act as redox indicators in the quantitative analysis of metal ions, e.g., ruthenium(III), antimony(III), silver, and organic substrates, e.g., ascorbic acid [38]. Oleophilic acylated leuco compounds of diaminophenazine dyes are suitable as color-forming agents in copying paper [39] and thermographic systems [40]. Basic safranines can also be used in laser technology [41] and in optical recording media with recording light having wavelengths shorter than 700 nm [42].

Monoamino- and diaminophenazine dyes bearing at least one phenyl residue on an amino group, in the form of their anhydro bases, are recommended for spin dyeing of polyacrylonitrile fibers in the gel stage [43].

Rhoduline Violet (Bayer, 1894), or *Leather Red Violet HM* **16**, C.I. 50 250 [*23279-70-1*] (Hoechst), is synthesized by reaction of 4-nitrosodimethylaniline with 3-amino-4-methyldiphenylamine.

24

The amino group is diazotizable. By coupling with aromatic amines, phenols, and *N*-heterocycles, the safranine azo dyes are formed (Janus Black G, Janus Green B, Diazine Black K). The dyes can be used for dyeing polyacrylonitrile [44] and acid-modified polyester fibers [45] and as light filters with variable optical density [36].

Janus Black R **17**, C.I. 11 825 [*4443-99-6*], is formed by coupling diazotized diethylphenosafranine to phenol.

25

The dye was commercially available as Sumiacryl Black G (Sumitomo) and as Aizen Cathilon Grey BLH (Hodogaya) for the dyeing of polyacrylonitrile fibers.

By coupling the same diazo compound to *N*-methyl-*N*-cyanoethylaniline, Aizen Cathilon Navy Blue GLH (Hodogaya) is obtained, and by coupling to *N*,*N*-dicyanoethylaniline, Sumiacryl Navy Blue R (Sumitomo). These dyes have also been recommended for dyeing polyacrylonitrile.

Similar dyes are used for determination of antimony or thallium by extraction of the ion associate [46] and as thermosensitive color indicators [47]. They also serve as lustering agents in galvanic copper-plating baths [48] and as accessories in electrolytic tin plating [49]. Safranine azo dyes are also used in color photography [50]. By diazotizing Rhoduline Violet and boiling down the diazonium salt solution, polymeric phenazine dyes are obtained, which are likewise used as lustering agents in galvanic copper-plating baths [51].

2.2.3. Acid Safranine Dyes

The introduction of sulfo groups converts safranines whose amino groups are arylated into fast violet- to blue-coloring wool dyes, which are especially suitable for seawater-fast bathing suits and piece goods (women's fabrics). Today the importance of these dyes has decreased. They are synthesized from sulfo-containing aniline and 1,4-phenylenediamine derivatives by oxidation to the indamine and cyclization to the azine by using a primary aromatic amine. If 1,3-dianilinonaphthalene-8-sulfonic acid is used instead of the aniline component, an indamine is obtained that already contains the nitrogen atom required for the formation of the azine ring, so that in this case a third component is unnecessary. A further route to acid safranine dyes is the exchange of the sulfo group in the 6-position in isorosinduline di- and trisulfonic acids in neutral or weakly alkaline medium for the sulfonic acids of *N*-alkylated 1,4-phenylenediamines. The oxidative condensation of alkylated phenylenediamines with isorosinduline bases followed by sulfonation is also used.

An example for an acid safranine dye made from three components is *Acid Cyanine BF* **18** (Agfa, 1906) [51], C.I. 50 230 [*6448-97-1*].

26

Preparation [52]**.** Neutral solutions containing the sodium salt of 61 kg of 4-nitro-4′-aminodiphenylamine-2-sulfonic acid in 500 L of water and the sodium salt of 57 kg of *N*-ethyl-*N*-benzylanilinesulfonic acid in 300 L water are combined in a 5000 L wooden vat equipped with a propeller stirrer. After the solution has been diluted with 1400 L of ice water, a solution containing 75.5 kg of sodium dichromate and 37.2 kg of sulfuric acid monohydrate in 4000 L water is added at 5 °C. After stirring the mixture for 15 min, a neutral solution containing the sodium salt of 30.5 kg of aniline-4-sulfonic acid in 290 L of water is added. The mixture is again stirred for 15 min, then heated to 40 °C and stirred for 15 min. After rapid heating of the mixture to 80 °C with live steam, 11 kg of sodium carbonate is added. The reaction mixture, cooled to 70 °C, is transferred to a 6000 L reduction vessel equipped with a propeller stirrer, mixed with 50 kg of iron filings, and stirred for 45 – 60 min. The alkaline spot test must show a brown rather a reddish blue spot. The reaction mixture is allowed to settle, then filtered through a filter press. The process of settling and filtration is repeated and the press is then washed, first with 1000 and then with 2000 L of water. The filtrate is salted out with 800 – 850 kg of common salt and, after stirring overnight at 18 – 20 °C, filtered under suction. After drying under vacuum, 180 – 190 kg of the dye is obtained, corresponding to 360 – 380 kg of commercial-type Acid Cyanine BF.

Other trade names were Acilan Fast Dark Blue BF and Aciderm Cyanine EZB (Bayer).

On this basis reactive dyes for cotton have been developed. Instead of aniline-4-sulfonic acid, 4-chloro- or 4-methoxyaniline-3-sulfonic acid has been used in this preparation procedure. The primary amino group is then allowed to react with cyanuric chloride, 2-methoxy-4,6-dichlorotriazine, or 2,6-dichloro-5-cyanopyrimidine [53]. The dyes obtained by reaction first with cyanuric chloride and then with 3-aminobenzenephosphonic acid or by reaction first with 2,4-dichlorotriazine and then with aliphatic or aromatic amines containing a sulfatoethylsulfonyl group are also recommended as reactive dyes for cotton [54].

Commercial products of this series were Procion Blue MX-7RX, PN PC, T-7RX (ICI).

The acid safranine dyes that are obtained by joint air oxidation of 1,3-bis(phenylamino)-naphthalene-8-sulfonic acid and 4-aminodiphenylamine-2-sulfonic acid or 1,4-diaminobenzene-2-sulfonic acid in the presence of copper oxide/ammonia still had significant sales about ten to fifteen years ago [55].

Supranol Blue BL (**19**, R = H) [*6378-88-7*] and *GL* (**19**, R = OCH_3) [*6856-08-2*], or *Wool Fast Blue BL* and *GL*, C.I. 50 315 and 50 320, were the most important dyes of this series. Of the latter about 40 t were produced in the Federal Republic of Germany in 1984.

27

Preparation [55]**.** Weakly basic solutions containing 0.87 kmol of 1,3-bis(phenylamino)naphthalene-8-sulfonic acid in 1700 L of water and 0.9 kmol of 4-aminodiphenylamine-2-sulfonic acid in 1000 L of water are combined in a 10 000 L iron kettle equipped with a propeller stirrer (95 rpm), and a solution containing 35 kg of copper sulfate and 40 kg of 40 % ammonia in 130 L water is added, followed by 40 kg of ammonium chloride and 3500 L of ethanol. After dilution to 7000 L with water, air is blown through the mixture at 40 °C for 6 h. Then, the reaction mixture is allowed to cool to 25 °C and salted out with 2000 L of 25 % common salt solution. After the mixture is filtered through a suction filter under pressure, the press cake is washed twice with cold water. Yield: 500 kg = 1350 kg Supranol Blue BL, commercial type.

Other trade names were *Aciderm Blue EBL* (Bayer), *Benzyl Blue BL* [*6378-88-7*], *Orasol Blue BLN* [*52218-73-2*] (Ciba-Geigy), *Coomassie Blue BL* (ICI), and *Xylen Fast Blue BL* (Sandoz).

Supranol Blue BL can be converted to a spirit-soluble form by reaction with longer chained aliphatic amines. Such a dye salt was commercially available as *Irisol Fast Blue BLN* [*6378-88-7*] for dyeing nitrocellulose lacquers. This dye is also suitable for dyeing and printing of synthetic polyamides from organic solvents, in particular chlorinated hydrocarbons [56]. Supranol Blue GL is similarly used to prepare *Irisol Blue GLE*. The dyes can be reduced to leuco compounds, which can be used to check the packaging of foodstuffs stored under oxygen-free conditions with regard to imperviousness of the packaging [57].

Wool Fast Blue FFG **20**, C.I. 50 330 [*6837-47-4*], is prepared, analogously to Supranol Blue BL, from 1,3-bis(phenylamino)naphthalene-8-sulfonic acid and 4,4′-diamino-3′-methyldiphenylamine-2-sulfonic acid [58].

28

The primary amino group can react with cyanuric chloride [59] or with cyanuric fluoride and subsequently with aminobenzenesulfonic acid [60] to give reactive dyes which dye cotton in clear blue shades.

The condensation that takes place during the formation of *Acilan Fast Violet FB*, or *Wool Fast Violet B* **21**, C.I. 50 325 [*6837-46-3*], from 1,3-bis(phenylamino)naphthalene-8-sulfonic acid and 2-methoxy-1,4-phenylenediamine-5-sulfonic acid proceeds differently. In the cyclization step the methoxyl group is split off as methanol. Therefore, the dye can also be synthesized from 1,4-phenylenediamine-2-sulfonic acid.

29

By reaction with longer chain aliphatic amines, the spirit-soluble dye *Irisol Fast Violet BBN* [*71839-03-7*] is obtained.

Dyes of the type of formula **19** or **21** can be used as main component in blue toners for the electrophotography [61] or as tinting dyes in fluorescent whitening.

Supranol Fast Cyanine B or *Indocyanine B* **22**, C.I. 50 335 [*6378-89-8*], (Agfa, 1902), is synthesized by the following reaction sequence: 2-phenylaminonaphthalene is condensed with 4-nitrosoethylbenzylaniline to give the indamine, which is oxidized with manganese dioxide to the isorosinduline (Blue I, **22**). Subsequent reaction with 4-aminodiethylaniline and 4-nitrosodiethylaniline gives the safranine (Blue II, **22**), which is then disulfonated to **22** [62]. The dye is used as an accessory for the galvanization of copper [63].

30

31

32

Fast Wool Blue EB **23**, C.I. 50 300 [*6471-74-5*], and *Supramine Blue EG* **23**, C.I. 50 310 [*6378-87-6*], are prepared according to the same method [64].

33

34

Supramine Blue EG was selected as Standard 4 for the eight-step ISO lightfastness test [65].

The dyes *Novazol Acid Blue GL* (**24**, R = C_2H_5) and Polar Blue G (**24**, R = $CH_2C_6H_5$), developed by Geigy, are obtained from diethylisorosinduline-1,6-disulfonic acid **24**, prepared according to [66], by exchange of the sulfonic group in the 6-position for 4-aminodiethylaniline-3-sulfonic acid and 4-aminoethylbenzylaniline-3-sulfonic acid [67], respectively. The second sulfo group in the 16-position can also be introduced by sulfonation in oleum [68]. This improves the alkali fastness and shifts the tint form a dull reddish blue to a pure greenish blue.

35

36

Acid safranine dyes, e.g., **23**, are recommended for use in inks for ink-jet printers [69]. They are useful as indicators in the quantitative analysis of metal ions such as As(III), Sb(III), Tl(I) and organic substrates like hydroquinones and ascorbic acid [70]. They have also been combined with monomeric acrylic acid derivatives or unsaturated polyesters, and deep-colored polymers have been prepared in this way [71].

2.2.4. Indulines

Induline dyes, the product of the reaction of aniline hydrochloride and aminoazobenzene, consist of a complex mixture of phenazine dyes, the composition of which continuously changes with progressive reaction. *Induline 6B* **26**, which is substituted with four aniline groups, is finally

formed. The reaction begins with the reduction of 4-aminoazobenzene to 1,4-phenylenediamine, which is oxidized to the quinone imine. Then, addition of aniline and oxidation to give the quinone alternate until 2,5-dianilinobenzoquinone-1,4-iminemonoanil **25** and -dianil (**25**; azophenine) are formed. After azine ring closure and oxidation, **25** gives *induline* (**25**; Hoechst, 1889), while **25** is converted to aminophenylaposafranine **25**.

In addition, the following dyes could be identified in the induline melt: *Indamine Blue B, R*, *Nigrosine Base G* **26** (BASF), C.I. 50 204 [*6471-73-4*], *Induline Base 3B*, *Fast Blue Base RF* **26** (BASF), C.I. 50 400 [*8004-98-6*], *Induline Base N* (BASF), *Induline Base 6B* **26**, C.I. 50 400 [*8004-98-6*].

Induline Base 5BM consists of a mixture of the above-mentioned induline dyes, Induline base 6B being the main component.

Induline Base 6B was synthetically prepared by an independent route by condensation of 4,5-bis(phenylamino)-*o*-benzoquinone with 2-amino-5-chlorodiphenylamine followed by reaction with aniline hydrochloride [72].

Indulines which are soluble in benzene or spirit are synthesized by alkylation [73], e.g., with alkyl halides [74].

Induline bases are primarily used for dyeing of plastics. They are recommended as charge-controlling agents in positive toners for electrophotography [75]. Salts with oleic acid can be used in typewriter ribbons or carbon paper [76].

By sulfonation of the bases, acid induline dyes are obtained, which are used for the dyeing of leather. They are useful for improving the light stability of photographic paper [77] and for adjusting the contact angle of inks for ink-jet applications [78].

2.2.5. Nigrosines

Nigrosine dyes, the products of the action of nitrobenzene on aniline in the presence of iron(II) chloride and hydrochloric acid, also consist of a complex mixture of phenazine dyes. The thin-layer chromatogram shows a large number of components that are also present in induline, in particular Induline 6B **26**. In contrast to induline, however, the dye mainly consists of higher molecular mass phenazines, which remain at the starting spot of the chromatogram.

A distinction can be made between water-, ethanol-, and fat-soluble nigrosines. The ratio of aniline to nitrobenzene and the melting temperature differ only negligibly for the three kinds.

The crude melt, a mixture of nigrosine hydrochlorides, is offered as *Phenol Black L* for the dyeing of phenolic resins.

Preparation. In a 3000 L steel enamelled kettle equipped wth a stirring apparatus, an indirect heater, and a 3.0 MPa steam heat exchanger, 2000 L of aniline, 231 L of 30 % hydrochloric acid, and 132 kg of iron(II) chloride are heated over 2 – 3 h to 165 °C, and the water, together with azeotropically codistilled aniline, is distilled. Over 5 h, 588 L of nitrobenzene is introduced at 165 °C with stirring. Because of the exothermic reaction, the temperature increases to 170 – 180 °C; it is then adjusted to 186 °C over the course of 4 h, and maintained for 2 – 3 h at this temperature. The melt is subsequently diluted with 1400 L of aniline and drawn off into 4000 L of water which has been placed in a 6000 L steel enamelled kettle equipped with a stirring apparatus. The reaction kettle is washed with 100 L of aniline, and this, along with the aniline water from the distillation condenser, is added. The reaction mixture is now heated to 95 – 100 °C and stirred for 1 h at this temperature, and the charge is allowed to stand for 24 – 36 h to separate the phases. The lower layer is drawn off into a 4000 L paddle dryer; the upper aniline – water layer is fed to an aniline recovery unit. In the paddle dryer, the melt is heated in a vacuum of 27 kPa with steam of 100 kPa overpressure to 100 °C jacket temperature. After 2 – 3 h, the temperature is increased to 140 °C and maintained at this temperature for 18 h. The melt is cooled over 6 h, the vacuum lifted with nitrogen, and the paddle dryer emptied. Yield: 1150 kg Phenol Black L; 2700 kg of aniline is recovered.

The preparation of nigrosine dyes can also be carried out continuously by passing the reaction melt successively through two reaction zones at different temperatures. In the first zone, the melt is heated for 6 h at 150 – 160 °C, and in the second for 12 – 13 h at 180 – 200 °C [79]. The workup of the nigrosine melt can also be carried out continuously by mixing the aniline-containing dye melt with an aqueous medium and separating the aqueous phase from the aniline-containing phase in a suitable separation apparatus [80].

Removal of excess aniline can be carried out by grinding the melt with aqueous acid in a ball mill [81]. A pyrophoric nigrosine base can be freed of this disadvantageous property by dissolving it in aniline and introducing air for 16 h at 75 °C. Subsequently, the solution is evaporated to dryness under vacuum [82]. A nigrosine granulate is obtained if the nigrosine melt, prepared by reaction of aniline with *p-tert*-butylnitrobenzene at 180 – 185 °C, followed by treatment with caustic soda, is heated to 240 °C and extruded into cold water through a 3 mm nozzle [83]. By the addition of phthalic anhydride to the nigrosine melt, a readily dispersable, flowable form is obtained [84].

The replacement of 5 – 15 % of the aniline with *o*-nitrochlorobenzene supposedly results in better yields for the nigrosines and indulines [85].

The nigrosine bases serve for preparation of printing colors and for dyeing of plastics. They are used as broadband-absorbers in thermal optical limiters for laser application [86] and as additives in the dispersion polymerization of styrene and butyl methacrylate to yield monodisperse micrometer-size beads with narrow size distribution [87].

The preparation of water-soluble nigrosines starts from the crude nigrosine melt. In this case, the preparation is similar to that of Phenol Black L; however, before evaporation in a paddle dryer, the hydrochlorides are converted to the base by treatment with caustic soda. In order to facilitate separation of the aqueous phase, the viscous melt is first diluted with aniline.

By sulfonation of the thus-prepared Lake Black Crude, *Nigrosine WLF* and *W liq.* [*8005-03-06*] are obtained.

The dyes serve for the dyeing of paper and leather [88]. They are used as cheap darkening agent for olives [89]. Arylguanidine salts of sulfonated nigrosines, e.g., with di-*o*-tolylguanidine, afford ballpoint pen inks with black shades having high color strength. They exhibit infrared absorption [90].

Nigrosine dyes containing sulfonic acid groups can also be prepared by treating nigrosine bases with diazotized sulfanilic acid in the presence of pyridine, adjusting the pH to 10 by the addition of alkali, separating the pyridine base, and salting out the dye. This dye is used for inkjet printing [91]. Ammonium salts of the nigrosine sulfonic acids serve for the preparation of waterproof flexographic inks [92]. Solutions of

acid nigrosine dyes containing a polyvinylpyrrolidone resin are aqueous printing colors for ink-jet printing [93].

The ethanol-soluble nigrosines are the purified hydrochlorides of the nigrosine bases. Complete removal of the iron salts is a determining factor for the solubility in spirit. Important commercial products are *Brilliant Spirit Black RM*, *Lake Black H* (Lanxess), and *Basonyl Black X22* (BASF).

Preparation of Brilliant Spirit Black RM New. In a 1000 L cast-iron melting kettle equipped with a gate agitator, a condenser, and a heating coil (2.5 MPa steam), 570 kg of aniline, 182 kg of 30 % hydrochloric acid, 16 kg of dry iron(II) chloride, and 16 kg of iron turnings are slowly heated to 120 – 125 °C with stirring until the water is distilled off. Then, the reaction mixture is rapidly heated to 180 °C, 180 kg of nitrobenzene is added in a thin stream over 4 – 5 h at this temperature, and the mixture is maintained for an additional 3 h at 180 – 185 °C inner temperature. The reaction water together with some nitrobenzene and aniline is distilled off through a descending condenser. The nitrobenzene – aniline mixture, which separates from the water, is returned for reuse in the reaction process. After completion of the melting, the contents of the kettle are transferred to a 7000 L stone-lined cast-iron kettle equipped with a mechanical stirrer and containing 1500 L of water and 500 L of 30 % hydrochloric acid. The charge is stirred for 8 h at 95 °C and pressed hot in filter presses; the press cake is washed with water to remove the aniline, boiled with 1500 L of water and 75 kg of 30 % hydrochloric acid for 2 h, pressed out, and washed to neutrality. After drying under vacuum at 90 °C, 330 kg of Brilliant Spirit Black RM New is obtained. By neutralization of the salt liquor with lime followed by steam distillation, 340 kg of aniline is recovered.

An ethanol-soluble nigrosine granulate is prepared by first treating the washed, wet nigrosine paste with a paraffin wax melt in the presence of nonionic surfactants, then drying and grinding [94].

The fat-soluble brands consist of the nigrosine bases that have been obtained from the hydrochlorides by treatment with soda. Commercial products are *Nigrosine Base BA* (Lanxess).

By heating the nigrosine bases with fatty acids such as stearic acid or oleic acid, fat-soluble black brands are obtained. Important commercial products are *Nigrosine Black BA liq.*, *Nigrosine Black A liq.* (Lanxess), *Neptune Black X14*, *X16* (BASF).

Such dyes are useful for ink-jet application [95]. Salts of organic acids or acylated nigrosines are suitable as developers for electrostatic copying processes [96] and as colored charge-controlling agents in positive toners for electrophotography [97].

Nigrosine salts of long-chain alkyl sulfonic acids, prepared by reaction of nigrosine bases with these acids, are used for oil-soluble inks [98] or in microencapsulated form for pressure-sensitive copying material, which can be read in the infrared [99].

Induline and nigrosine dyes containing sulfonamide groups are prepared by reaction of induline and nigrosine sulfonyl chlorides with primary and/or secondary aliphatic or cycloaliphatic amines. They are suitable for the preparation of lack and printing dyes, ballpoint pen pastes, and mimeographic colors [100].

Spirit-soluble nigrosines, which are especially valuable for the preparation of inks and ballpoint pen pastes, are obtained by reaction of nigrosine bases with propylene oxide or butylene oxide [101].

2.2.6. Aniline Black

Aniline Black [*13007-86-8*] is the term for a group of dyes that are formed by oxidation of aniline, *o*-toluidine, *m*-toluidine, *p*-phenylenediamine, 4-aminodiphenylamine, and similar bases of the benzene series. The involved structures were the subject of several studies. It is believed that, starting from indamine structures such as emeraldine **27**, further oxidation and condensation with aniline form phenazine structures like **27** and **27** and finally insoluble polymeric compounds [102]. Aniline Black is mostly produced on the fiber itself in printing and in dyeing; for example, on cotton as well as on synthetic fibers, especially polyester fibers. In addition, for the dyeing of lacquers, plastics, and paper Aniline Black is produced in substance.

For the one-bath dyeing of cotton yarn, the fibrous material is treated with a solution of

44

45

46

dichromate, aniline, hydrochloric acid, sulfuric acid, and copper sulfate, first in the cold, then at 70 °C. Finally, the material is washed and soaped. This black color greens under the influence of reducing agents. According to another dyeing process, the cotton fabric is placed in a bath containing aniline, aniline hydrochloride, sodium chlorate, ammonium chloride (as acid source), aluminum acetate, and a copper or vanadium salt as catalyst. The fabric is padded, dried, steamed, then possibly treated with chromium salts to complete the oxidation, and finally soaped. The colors thus obtained possess better fastness properties. To protect the fibers from damage by the mineral acids present, nonprecipitable proteins, urea, and dextrose have been recommended [103]. The general dyeing procedure is described in [104]. Improvements have been made by avoiding the steaming step, which results in energy conservation and reduction of air pollution by aniline vapor [105].

The production of black tints on polyester materials can be achieved with soluble derivatives of 4-aminodiphenylamine, e.g., azomethines of sulfobenzaldehydes (e.g., the former *Resolin Black Base*, Bayer), which are oxidized by quinonedichloroimide (e.g., the former *Resolin Black Developer*, Bayer) [106].

Helio Fast Black TW, a color-strong Aniline Black pigment, is obtained by replacing part of the aniline with *o*-toluidine. The pigment contains a significant amount of chromium, which comes from the oxidizing agent sodium dichromate; the amount can be decreased by stirring with 3 % hydrochloric acid.

Preparation. 3750 L of water and 436 L of 30 % hydrochloric acid are placed in a 8000 L enamelled kettle equipped with a mechanical stirrer, and 150 kg of aniline and 52 kg of *o*-toluidine are then added. With further stirring, 78 kg of sulfuric acid monohydrate is added, and the contents of the kettle are heated to exactly 27 °C. Starting at this temperature, a 24.5 % solution of sodium dichromate is added in several portions, and the solution is stirred each time for 15 min before the next amount follows. The temperature increases to 29 °C with the addition of 318 kg of sodium dichromate solution; further addition of three times 273 kg raises the temperature to 33, 39, and 45 °C. Then the pigment is immediately isolated in a filter press, washed with 3000 L of water, and dried by blowing. The dried pigment is mixed with 6000 L of deionized water and 500 L of 30 % hydrochloric acid and stirred overnight at 25 °C. The press cake is

washed with 8000 L of distilled water, and the pH of the mixture is raised to 5 with 5 kg of sodium carbonate. The isolated product is dried under vacuum at 90 – 95 °C. Yield: 280 kg Helio Fast Black TW.

An ash-poor Aniline Black is obtained by oxidizing aniline with potassium dichromate in the presence of copper(II) sulfate and sulfuric acid; the dichromate and sulfuric acid are added in three portions over 5 h at 50 °C [107]. The oxidation can also be effected with sodium hypochlorite instead of potassium dichromate [108]. Finally, a chromium-free Aniline Black can also be obtained by oxidation, first with H_2O_2 in the presence of copper sulfate, and subsequently with atmospheric oxygen [109].

A black pigment having a similar constitution is formed by oxidation of *o*-ethylaniline with sodium chlorate in acidic medium in the presence of copper sulfate [110].

Aniline Black is used in dry toners for electrophotographic laser printers [111], in pigment inks for ink jet printers [112], and bound to a protein in the production of an antiserum for cancer therapy in warm-blooded animals. Aniline Black is an electrical conductor with holes as the main charge carriers [113]. It can act as the cathode material of rechargeable lithium batteries [114].

2.2.7. Oxidation Dyes

Oxidation dyes are organic compounds that are converted into the dyeing substance on the substrate being dyed. They are used for dyeing furs because with these products the natural character of fur pelts can be especially well imitated or improved on. Today they are increasingly being displaced by acid dyes, but especially the luster and coverage of oxidation dyes are still superior.

In their fundamental patents Monnet in 1883 [115] and Erdmann in 1888 [116] made known a process for dyeing hair and feathers with aqueous or alcoholic solutions of aromatic diamines in which the dyeing substances, after being absorbed by the material, are oxidized with atmospheric oxygen, hydrogen peroxide, iron chloride, permanganates, hypochlorites, or dichromates. Because the small dye precursors penetrate deep into the hair and are oxidized there to larger colored compounds, the coloring is extremely durable to light and washing. The Ursol dyes, developed by Agfa, by Farbwerke Hoechst, and later by IG Farbenindustrie, were produced in the past, e.g., by BASF and are now produced by Dohmen. They also contain, besides diamines, aminophenols and their nitro and chloro derivatives as well as their salts with hydrochloric and sulfuric acids.

Fur Dyes. The most important dye is *Ursol D* or *Benzofur D* [*106-50-3*], 1,4-phenylenediamine. Other brand names were or are, e.g., Pelagol D, Pelagol Grey D, Peltol D, Tertral D, Durafur Black R, Fouramine D, Furro D, Futramine D, Nako D, Developer PF. On oxidation, it is converted via the quinoneimine into Bandrowski's Base **28**, X = NH), which, on further oxidation, forms phenazine dyes [117].

Ursol D is also present as a component in numerous other Ursol dyes, e.g., *Ursol A, DF, DG, NZ, NZD, RH, RHG, SK*, and *SKG*.

p-Aminophenol is commercially available as *Ursol P* or *Benzofur P* [*123-30-8*]. On oxidation, it forms first the quinonemonoimine, which, following an analogous path as described above, yields hydroxy compound **28** (X = O), which is analogous to Bandrowski's Base. This is converted into oxazine compounds on further oxidation [118]; cf. [4].

Some Ursol dyes, such as Ursol EG (*m*-aminophenol) [*591-27-5*], Ursol EWG (chlororesor-

cinol and resorcinol), Ursol ERN (1-naphthol) [*90-15-3*], and Ursol SLA (2,4-diaminoanisole sulfate) [*6219-67-6*], have inherently only a small dyeing ability, but in combination with other Ursol dyes effect a deepening as well as a shifting of the color shade; e.g., Ursol EG shifts gray to blue and black to olive brown. Only with such or similar combinations are pure blue or red shades available [119]. Substituents in the 4-position in such *m*-disubstituted benzenes stop further condensation on the level of indamines or indophenols **29**. Fur dyeing with simultaneous silvering of hair ends is achieved by treatment with metal salts, 4-amino-2-methoxydiphenylamine, and a condensation product of formaldehyde with resorcinol and cresolsulfonic acid [120].

The *Ursatin dyes*, introduced commercially in 1935 by IG Wolfen, can also be used to effect combinations of shades. These are the salts of dihydroxynaphthalenes with aromatic or heterocyclic amines. *Ursatin Brown B* has, e.g., the following composition: 40 % of the salt consists of 1,5-dihydroxynaphthalene and toluylenediamine, and 60 % consists of a mixture of the sodium salts of the sulfonic acids obtained by sulfonation of coconut oil monoglyceric esters and naphthalene with fuming sulfuric acid (10 % SO_3). Important Ursatin dyes are *Ursatin Brown B, Yellowish Brown G, Blue RN, Violet B*, and *Red BB*.

Other fur assortments were *Nako* (Hoechst), *Durafur* (ICI), *Fourramine* (Francolor), *Eukamine* (Geigy).

Cosmetic Hair Dyes. For cosmetic hair dyes, the oxidation dyes are commercially available in the form of solutions or pastes. Ursol dyes used for this purpose include *Ursol D*, *Ursol 4G* (1-nitro-3,4-diaminobenzene hydrochloride), *Ursol 4R wet* (picramic acid), *Ursol 2G* (2,4-toluylenediamine), *Ursol P-Base, Ursol Brown RR* (2-nitro-1,4-phenylenediamine) [*5307-14-2*], *Ursol EG*, and *Ursol EWG*. For a historical review, see [121].

Azine and oxazine dyes are obtained on oxidation of equivalent amounts of diaminobenzenes or aminophenols and dihydroxybenzenes with hydrogen peroxide, the skin-irritating Bandrowski's Bases being avoided. Example: 2-methyl-1,4-phenylenediamine and resorcinol [122]. By preoxidation of a molar mixture of a 1,4-diamine (e.g., 2,5-toluylenediamine) and either a 1,3-diamine (e.g., 2,4-diaminoanisol), a 1,3-aminophenol, or a 1,3-dihydroxybenzene with 1 – 2 mol of O_2, a colored preparation is obtained [123] that produces permanent hair colors [124].

Commercial products of this series were *Ursol NZS* and *Ursol RHS* (BASF).

Aminophenols [125] and diaminophenol ethers [126] that bear a methyl group on the aromatic ring can be used as coupling components in hair coloring agents. 1-Methyl-4-isopropyl-2-hydroxybenzene is also recommended as a coupling substance [127]. The tolerance of skin toward the couplers based on phenylenediamine is improved by the introduction of alkyl ester groups into the benzene ring [128] or into the amino group [129] or by alkylation of the amino group [130]. The introduction of sulfo groups serves the same purpose. *N*,*N*-bis(2-hydroxyethyl)-*p*-phenylenediamine is used as a partial replacement for *p*-phenylenediamine [131]. Aminonaphtholmonosulfonic and -disulfonic acids are used as couplers [132].

4-Amino-3-methylpyrazolone hydrochloride and its *N*-substituted derivatives [133] as well as 3-aminopyrazoline [134] are physiologically compatible heterocyclic amines for dyeing hair.

An example of a heterocyclic hydroxy compound is 6-hydroxyquinoline [135]. 2,4,5,6-tetraminopyrimidine as developer and 2,6-diaminopyridine as coupler yield shades with high vividness and excellent fastness [136]. The same is true of hydroxyaminopyrimidines, e.g., 2-hydroxy-4,5,6-triaminopyrimidine [137], and diaminopyrazoles [138], which additionally have excellent physiological tolerance properties. 6-Amino-2,2-difluoro-1,3-benzodioxole is a coupler with improved fastness to washing and light and good substantivity [139].

Also suitable for hair dyeing are indamines, indoanilines, and indophenols, the initial reaction products of the hair dyes described above. Indamine salts are formed by the joint oxidation of aromatic diamines and aminohydroxy compounds [140]. Indamines with ring-cyclized amino groups are obtained by the use of 6-hydroxytetrahydrobenzoxazine [141]. The joint oxidation of phenylenediamine and phenols by ammonium persulfate affords the indaniline dyes [142]. Their leuco compounds, the aminohydroxydiphenylamines, are also suitable as hair dyes [143]. Indophenols are formed by the joint oxidation of aminophenols and phenols [144].

In the 1980s several compounds for cosmetic hair dyes have been banned in Europe for toxicological reasons, including 2,4-diaminotoluene and 2,4- and 2,5-diaminoanisole. Substitutes have been found, e.g., 2,4-diaminophenoxyethanol [145], 2-amino-4-β-hydroxyethylaminoanisole [146], 1,3-bis(2,4-diaminophenoxy)propane [147], 2-β-hydroxyethyl-*p*-phenylenediamine [148], and 3,4-diaminophenols bearing aminoalkyl or mono-, di-, or trihydroxyalkyl substituents on the N and O atoms [149].

A new study shows a significant increase of bladder cancer caused by the repeated use of permanent (oxidation) hair dyes over several years [150].

Because the use of hydrogen peroxide at high pH damages the hair and irritates the scalp, procedures using oxidative enzymes instead of peroxides have been developed which work at neutral pH values [151]. Oxidoreductase enzymes are recommended for the same reasons [152].

2.3. Aminohydroxy- and Monohydroxyphenazine Dyes

Phenazine dyes with an amino and a hydroxyl group as auxochromes are virtually completely present in the phenazone structure (**1**, where D^2 is =O). They are obtained by reaction of nitrosophenols with *m*-toluylenediamines that are alkylated in the position *para* to the methyl group to give indophenols, followed by oxidation to give the azine dye. Dyes of this kind having a naphthalene ring system are obtained if the isorosinduline dyes, prepared from alkyl- or aryl-2-naphthylamines and nitrosodialkylanilines, are treated with alkali under the action of oxygen. None of these dyes has industrial importance any more. However, phenazone compounds have been suggested for the delignification of lignocellulose materials [153]. Their use in recording materials has also been described [154].

3. Oxazine Dyes

The cationic mono- and diaminophenoxazine dyes are widely used to dye acid-modified synthetic fibers, especially polyacrylonitrile fibers containing acid groups [155]. Aminophenoxazine dyes are also suggested for dyeing polyolefin materials [156]. The earlier areas of application, the dyeing of tannin-mordanted cotton, silk, leather, and lacquers, are now only of minor importance.

The aminohydroxyphenoxazine dyes include the gallocyanines, which form light-stable metal complexes with chromium. They were mainly used for the dyeing and printing of wool, but also for the dyeing and printing of cotton; however, they have been replaced by acid anthraquinone dyes and by reactive dyes.

Diaminophenoxazine dyes have recently found application in laser technology. They complement the emission spectrum of rhodamine on the long-wavelength side [157].

Phenoxazine dyes function as desensitizers [158] and are used in optical recording media with recording light having wavelengths shorter than 700 nm [42]. Leuco phenoxazine dyes are used in acylated form as chromogenic substances in pressure-sensitive copying paper. In a photochemical oxidation step, an acyl group is

split off and blue dyes are formed. The benzoyl derivatives are preferably used [159]. However, the acyl moieties of aliphatic carboxylic acids are also used [160]. Suitable acylating agents include heterocyclic carboxylic acids derived from pyridine, furan, or thiophene [161]. These leuco derivatives can be used in electrically developable recording materials [162] and in dye transfer printing processes [163].

Aminophenoxazine dyes [164] and hydroxyphenoxazine dyes [165] are also suitable in the form of their leuco compounds as highly sensitive oxygen detectors. The dyes are also used for the analytical determination of ascorbic acid [166] and as anodic electrochromic materials in electrochromic devices such as rearview mirrors, sun roofs, or windows [167].

Furthermore, diaminophenoxazine dyes are used for the staining of preparations in microscopy. They have recently also become of interest in chemotherapy. Compounds such as **30** are thought to inhibit tumor growth and to be effective against tubercular bacilli. The activity of several dyes exceeds even that of streptomycin [168].

51

$R^1 = R^2 = H, CH_3$
R^3 = Benzyl, 4-Chlorophenyl, H

3.1. Monoaminophenoxazine Dyes

Monoaminophenoxazine dyes are synthesized by reaction of nitrosodialkylanilines with aromatic hydroxy compounds, in particular compounds of the naphthalene series.

Fast New Blue 3R **31**, C.I. 51 175, first described in 1879, is the reaction product of 2-naphthol with excess 4-nitrosodimethylaniline, which functions simultaneously as oxidizing agent. It is used for dyeing polyacrylonitrile and, mixed with brown or yellow basic dyes, for the production of black tints on leather.

52

Preparation. 100 kg of dimethylaniline, dissolved in 260 kg of 30 % hydrochloric acid, is nitrosated with 58.4 kg of sodium nitrite in the form of a 40 % solution at 3 – 5 °C over 8 – 10 h. The reaction mixture is stirred for 1 h and allowed to stand overnight. It is then suction filtered and the product is washed with a dilute solution of common salt and finally with 200 L of ethanol. The nitroso compound, wet with ethanol, is made into a paste with 77 kg of zinc chloride and 250 – 300 L of ethanol and during 90 – 95 min added in 35 – 40 portions to a boiling solution containing 90 kg of 2-hydroxynaphthalene in 400 L of ethanol. The product is filtered hot through a closed suction filter under pressure, washed with a dilute solution of common salt containing zinc chloride, dried by suction, and made into a paste in a mixer with 13.2 kg of dextrin (to bring to commercial standard) and 5.4 kg of machine oil (to free from dust), and dried for 90 h at 55 – 60 °C.

Yield: 185 – 192 kg of commercial product. Moreover, the intermediate isolation of the nitroso compound can be eliminated [169].

The dye was offered as *Leather Dark Blue H3R* (Hoechst) and, for the dyeing of polyacrylonitrile, in dye mixtures. Furthermore, it is reported to be an intermediate hydrogen carrier for the determination of glucose-6-phosphate dehydrogenase [170] and a colored charge-control agent in toners for electrophotography [171]. The dye synthesized in a similar way from nitrosodiethylaniline is used in a solid laser composition [172].

Blue to black dyes suitable for dyeing cellulose acetate are obtained by condensation of nitrosodimethyl- or diethylaniline hydrochloride with 1,5-dihydroxynaphthalene in aqueous alcoholic solution containing at least 30 % water, preferably with the addition of manganese dioxide as catalyst [173]. The presence of water is necessary; otherwise, gray dyes are formed.

The position *para* to the nitrogen atom in the naphthalene ring is activated. By reaction

with amines, entry is achieved into the series of diaminophenoxazine dyes (see Section 3.2). By reaction with Michler's hydrol [bis(4-dimethylaminophenyl) methanol] *Fast New Blue R* (Bayer, 1892) is obtained. Sulfur-containing substituents can also be introduced into this position; e.g., Fast New Blue 3R can be treated with arylsulfinic acids, thiophenol, thiosalicylic acids, thioacetic acid, or thiourea. The initially formed leuco compounds are oxidized with iron chloride or nitric acid [174].

3.2. Diaminophenoxazine Dyes

Diaminophenoxazine dyes are synthesized by reaction of nitrosodialkylanilines or nitrosodialkylaminophenols with aromatic amines or aminophenols in alcoholic solutions or mineral acids. They are characterized by very clear hues.

Rhodulin Pure Blue 3G **32** (Bayer, 1916), C.I. 51 004 [*444-00-2*], is obtained by the action of 4-nitroso-1-diethylamino-3-ethoxybenzene on 3-diethylaminophenol in alcoholic hydrochloric acid, whereby the ethoxyl group is cleaved off.

53

Rhodulin Pure Blue 3G, also called *Oxazine 725*, is at present the most important cationic oxazine dye and is represented in all large assortments of polyacrylonitrile dyes. Examples are *Aizen Cathilon Blue 5G* (Hodogaya), *Astrazon Blue BG* (DyStar), *Diacryl Brilliant Blue 5G-E* (Mitsubishi), *Sumiacryl Blue E-6G* (Sumitomo), *Maxilon Blue 5G* (Ciba), *Sevron Blue 5G* (Crompton & Knowles), and *Yoracryl Blue 5G* (Yorkshire).

A similar product was *Basacryl Blue MX-8GF* (BASF).

According to a newer preparation procedure for Rhodulin Pure Blue 3G, the intermediate isolation of the nitroso compound can be dispensed with, and the dye is converted into the hydrochloride by precipitation of the zinc as its carbonate.

Preparation [175]**.** 114 kg of a 40 % aqueous solution of sodium nitrite is introduced into a solution containing 125 kg of *N,N*-diethyl-*m*-aminophenetidine in 150 kg of ethanol and 168 kg of 30 % hydrochloric acid at 0 – 3 °C. After the solution has been stirred for 1 h, 7.5 kg of soda is added to raise the pH to 2 – 4. The suspension obtained is added in small portions to a boiling solution containing 100 kg of *m*-diethylaminophenol in 300 kg of ethanol. When the reaction is complete, the mixture is cooled to 50 °C, 50 kg of zinc chloride is added with stirring, the mixture is allowed to cool to 20 °C, and the dye is filtered off under suction in the form of the zinc chloride double salt and washed with ethanol. The wet suction-filter cake is suspended in 4000 L of water, and ammonium carbonate (ca. 90 kg) is added at 60 °C until the filtered solution gives no more zinc carbonate precipitate after further addition of ammonium carbonate. The solution is filtered at 60 °C and the readily soluble dye is isolated by spray drying.

Addition of acetic anhydride during the condensation step is advantageous [176]. The nitrosation and further condensation to give the oxazine dye can also be carried out in a cyclic ether (dioxane), in sulfolane, or in an alkyl-substituted amide (dimethylformamide) [177]. If the condensation is carried out in the presence of zinc chloride and zinc oxide in methyl glycol, the dye precipitates directly as the chlorozincate in very pure form [178]. Oxazine dyes like **32** can advantageously be isolated as bromide salts because of their low solubility. These low-salt products can be used directly for dyeing or for the preparation of liquid dye formulations, e.g., by reaction with potassium acetate [179]. If the condensation is done in a mixture of a water-miscible solvent (dimethylformamide) with water or an alcohol in the presence of nitric acid, pure dyes of high color strength are obtained as nitrate salts [180]. Tetrachloroferrate salts can be isolated in pure form and are recommended to avoid contamination of wastewater with zinc salts [181]. Liquid preparations can be obtained starting from chlorozincate salts by extraction of the salts of oxazine dyes with monocarbonic acids into glycol ethers, while the metal is kept in the water phase by use of a complexing agent [182].

Instead of 3-ethoxydiethylaniline, hydroxyalkyl ethers, prepared by reaction of 3-hydroxydiethylaniline with alkylene oxides, can be used. This reaction can be carried out as the first

step of a one-pot procedure leading to the finished dye [183]. The zinc-free dye is obtained by precipitation with urea or thiourea [184].

Rhoduline Pure Blue 3G tints are characterized by a frequently desired green shade in artificial light. The dye is therefore often used in mixtures for dyeing polyacrylonitrile fibers in blue [185] and black [186] tints. As the salt of the dialkyl ester of sulfosuccinic acid, Rhodulin Pure Blue 3G is used for dyeing acid-modified polyester fibers in chlorinated hydrocarbons [187]. The dye can also be used, especially in combination with yellow and red dyes, for dyeing human hair [188] or bones and tusks of vertebrates [189]. It may be useful for the preparation of infrared-fluorescent inks [190], as sensitizer [191], or as charge-controlling agent [192] or photoreceptor [193] in electrophotography. It can also be used as laser dye, e.g., in solid-state dye lasers [194] or as dye in a mono- or multilayer optical recording media using fluorescent light for reading [195]. As a salt with surface active anions, e.g., dodecylbenzenesulfonate, the dye is used in thermal transfer printing on acceptor sheets containing ion exchangers [196].

Capri Blue GON **33**, C.I. 51 015 [*7199-02-2*] [197], is obtained by the action of nitrosodimethylaniline hydrochloride on 3-diethylamino-1-hydroxy-4-methylbenzene. The dye is commercially available as Sevron Blue NF (Crompton & Knowles) for dyeing polyacrylonitrile.

54

Diaminophenoxazine dyes whose amino groups bear a cyanoethyl group have proved to be especially valuable for dyeing polyacrylonitrile. For example, the dye prepared by condensation of 3-ethylmethylamino-4-methylphenol and 4-nitroso-*N*-ethyl-*N*-β-cyanoethylaniline hydrochloride in acetic acid and hydrochloric acid dyes polyacrylonitrile a clear blue [198]. Also worth mentioning are dyes prepared from *N*,*N*-bis(cyanoethyl)aniline [199] and from *N*-β-cyanoethyl-*N*-benzylaniline [200] according to the same procedure.

Commercial products of this series were *Remacryl Blue GGL* (Hoechst) and *Sevron Pure Blue 4G* (Du Pont).

Diaminophenoxazine dyes with primary and secondary amino groups are of particular industrial importance. Because of their low molecular mass, they migrate on polyacrylonitrile fibers and therefore result in especially level dyeing.

The dye **34** is prepared, e.g., by nitrosation of 3-hydroxydimethylaniline and condensation with 2,4-diaminoanisole [201] or with 2-methoxy-5-acetoxyaniline [202] in a polar, water-miscible solvent.

55

Another preparation procedure consists of the condensation in acetic acid of 3-hydroxydimethylaniline with the azo dye obtained by coupling diazotized *p*-sulfanilic acid to 2,5-dimethoxyaniline [203]. The indamine dye obtained by condensation of 3-methoxy-4-nitrosodimethylaniline with 2-amino-4-hydroxytoluene and precipitation as the chlorozincate complex can be isolated and subsequently converted into the oxazine dye **34** [204].

By mixing the dye with yellow and red low molecular mass cationic dyes, a wide palette of tints having high evenness is obtained [205].

Dyes have also been described that, instead of methoxyl groups, contain methyl groups in both nuclei [206]. The dye prepared from 4-nitroso-*N*,*N*-diethyl-*m*-phenetidine and 2-amino-4-hydroxytoluene is obtained by condensation in alcoholic solution in the presence of zinc powder [207]. 2-Methyl-4-nitrosomonoethylaniline, obtained by rearrangement of the corresponding nitrosamine in hydrochloric acid solution, affords, upon condensation with *m*-diethylaminophenol, a dye that colors polyacrylonitrile bright blue [208]. By joint oxidation of *p*-phenylenediamine and 2-amino-4-hydroxytoluene with $K_3[Fe(CN)_6]$ in ammonia solution, an oxazine dye is obtained that bears primary amino groups in the 3- and 6-positions [209].

Today the only commercially relevant product of this series is *Maxilon Blue M-G* (Ciba). Similar products were *Remacryl Blue B* [*51716-95-1*], *G* (Hoechst), *Remacryl Dark Blue E-GRL* [*64071-90-5*] (Hoechst), and *Maxilon Blue M-2G* (Ciba).

Oxazine dyes with cyclically bonded amino groups are suitable for dyeing polyacrylonitrile [210]. The dye **35** imparts a bright blue color to these fibers. It can also be used to dye hair [211].

56

Oxazine dyes with both amino groups incorporated in rings are used as laser dyes because of their rigid molecular skeleton [212]. Derivatives with sulfoalkyl groups on the ring nitrogen atom are also known [213].

Furthermore, triaminooxazine dyes are known that bear amino groups in the 2-, 3-, and 6-positions [214]. Their leuco products can be acylated to a ring-closed derivative suitable for electrochromic recording materials [215].

Diaminophenoxazine dyes **36** in which one amino group is substituted by a phenyl group, and which are prepared from the correspondingly substituted diphenylamino derivatives, impart to polyacrylonitrile tints having low brightness but increased lightfastness [216].

57

The dyes are suitable for transfer printing on polyacrylonitrile [217]. Their tetrafluoroborates can be used for the spin dyeing of the same fibrous material [218]. The action of alkalis on **36** produces a color base that can be used for spin dyeing [42] or transfer printing on textile material dyeable with cationic dyes, e.g., polyacrylonitrile [219], and on paper coated with an acidic layer [220]; the protonated dye is restored on the material. The color base can also be alkylated on the nitrogen atom by the action of dimethyl sulfate or ethylene oxide [221]. The same dye is obtained by starting from *N*-alkylated diphenylamino compounds [222]. Substituents in the *ortho* positions of the phenyl group, in particular methyl groups, improve the clearness of the phenylaminooxazine dyes, because the saddening effect of the phenyl group is reduced by steric hindrance [223].

A commercial product of this series is *Kayacryl Light Blue 4GSL* [*12221-43-1*] (Nippon Kayaku).

Nile Blue A **37**, C.I. 51 180 [*2381-85-3*] (BASF, 1888), is prepared by reaction of 4-nitroso-3-hydroxydiethylaniline with α-naphthylamine [224]. The dye is used in microscopy, immunoassays [225], and in laser technology [226]. It is also suitable for the prevention of deposits during the polymerization of vinyl chloride homo-, co-, and graft polymers [227].

58

Nile Blue BX is the ethyl homologue of this dye.

Diaminophenoxazine dyes, above all of those with a naphthalene ring system, are also obtained by reaction of monoamino dyes, in particular *Fast New Blue 3R*, with aliphatic or aromatic amines.

Thus, *New Methylene Blue GG* **38**, C.I. 51 195 [*62770-30-3*] (Casella, 1890), is formed by oxidation of the product obtained by condensation of Fast New Blue 3R **31** and dimethylamine:

59

By condensation of 4-nitrosodimethylaniline hydrochloride with 3-hydroxydiphenylamine in a molar ratio of 2:1, a basic dye is obtained that contains both structural features of an oxazine and a phenazine dye, but not of a bis-azine dye (see Chap. 5) [228]. It dyes tannin-mordanted cotton black.

60

3.3. Aminohydroxyphenoxazine Dyes

Aminohydroxyphenoxazine dyes largely have the phenoxazone structure (**1**, where D^2 is =O). Hydroxy- and aminophenoxazones exhibit characteristic key bands between 6.0 and 6.5 mm in the IR spectrum [229]. In nature, they are present as orceine dyes in lichens [230]. Aminophenoxazone dyes are suitable for dyeing textile material made from polypropylene [231].

By the introduction of another hydroxyl group in the position neighboring the OH group that functions as an auxochrome, the dyes acquire the ability to form color lakes with chromium salts. They can be made from derivatives of gallic acid and nitrosodialkylaniline salts and are therefore known as gallocyanines. Gallocyanine dyes are used as chrome dyes on wool and cotton. Their industrial importance has decreased; however, they have been recommended for the dyeing of polyolefins in the presence of heavy-metal salts [232].

Gallocyanine, Brilliant Chrome Blue P, C.I. 51 030 [*1562-85-2*] (Sandoz, 1881), is prepared by the action of 4-nitrosodimethylaniline hydrochloride on gallic acid in methanol [233].

Coelestin Blue B **40**, C.I. 51 050 [*1562-90-9*] (Sandoz, Durand, Huguenin & Co., 1893), is correspondingly obtained by action of 4-nitrosodiethylaniline hydrochloride with gallamide [234].

61

Preparation. In an enamelled 6000 L kettle equipped with a wooden gate stirrer, 110 kg of gallamide and 2000 L of alcohol (denatured, 94 %) are brought to a rapid boil. Over 10 h, 240 kg of nitrosodiethylaniline hydrochloride, dissolved in 1500 L of ethanol, is allowed to flow in. After addition of 21 kg of potassium carbonate, the reaction mixture is boiled for another 1 h and allowed to cool to 20 °C; 40 L of 20 % hydrochloric acid is added, and the mixture is pressed into a suction filter with a filtering stone bottom. After stirring with 500 L of 20 % hydrochloric acid, the mixture is filtered under suction until the product is well dried, and the product is further dried at 70 °C. Yield: 95 %. The ethanol is recovered by distillation.

The tetraphenylborates of dyes like **40** are recommended for use in electrophotographic toners [235].

Gallo Blue E, Prune Pure, C.I. 51 040 [*6416-51-9*] (Sandoz, 1887), is obtained by condensation of methyl gallate with the hydrochloride of nitrosodimethylaniline. The leuco compounds of these dyes were commercially available for some time as Mordant Violets; to improve their solubility, the dyes were also prepared as hydrogen sulfite compounds.

Delphin Blue **41**, C.I. 51 120 [*1323-96-2*], *Ultracyanol B* (Sandoz) is synthesized by blowing air through a hot mixture of gallocyanine hydrochloride and aniline, whereby the carboxyl group is exchanged by aniline, followed by sulfonation and conversion to the ammonium salt.

62

Chromazurin **42**, C.I. 51 125 [*1323-97-3*], *Chromazol Blue 5G* (ICI) is synthesized analogously but in the cold. Under these conditions the aniline group bonds to the position neighboring the carboxyl group, which is removed by subsequently heating to 100 °C.

63

By heating Nile Blue A **37**, the phenoxazone dye Nile Red **43**, is obtained. It is used as a laser dye in the near-infrared (702 nm) [236]. Perfluoroalkyl groups can be introduced into dyes like **43** in *ortho* position to the oxo group by reaction with bis(perfluoroalkylcarbonyl) peroxides [237]; e.g., with bis(trifluoroacetyl) perox-

ide a trifluoromethyl-substituted dye is obtained. These dyes have increased stability and light-fastness. Dyes of this type can also be used as red fluorescent dyes in inks, fluorescent labeling agents, fluorescent collectors, and sensors [238].

64

3.4. Mono- and Dihydroxyphenoxazine Dyes

Mono- and dihydroxyphenoxazine dyes occur in nature as orceine dyes [230]. Their use as food dyes is no longer allowed. The dyes are synthesized by reaction of nitrosophenols or nitrosonaphthols with phenols or naphthols. Another route is the reaction of 1,2-naphthoquinone-4-sulfonic acid with 1-amino-2-naphthol-6-sulfonic acid. *Alizarin Green G* **44**, C.I. 51 405 [*6492-63-3*], is thus obtained. It dyes chrome-mordanted wool a bluish-tinged green.

65

66

1,3,4-Trichloro-7-nitrophenoxazone-2 **44** [239] is a starting material for sulfur dyes. It is reduced and converted to the sulfur dye *Immedial Blue 5R* [*1327-96-4*] by polysulfide melt [240].

The dihydroxyphenoxazine dye resorufine serves as a chromogenic group for the analytical determination of a bacterial endotoxin [241]. Resorufin derivatives are used in diagnostics [242] and immunoassays [243].

4. Thiazine Dyes

The thiazine dyes are of minor importance today in the textile field because of their inferior fastness.

Silicon-containing diaminophenothiazine dyes, which can be prepared from *N,N*-dimethyl-*p*-phenylenediamine, *N*-(trimethylsilylpropyl)aniline, and thiosulfate by oxidation with alkali metal dichromate, are recommended for the dyeing of glass fibers [244].

Aminohydroxyphenothiazine dyes are present in the phenazone form (**1**, where D^2 is =S). If they contain a second hydroxyl group in the position *ortho* to the auxochromic OH group, they have mordant-dyeing properties.

Sulfur dyes that are prepared by fusion of 4-amino- and 4-nitrophenols with sulfur and sodium sulfide contain a thiazine ring system, which is, however, not in the form of the mesomeric azine system.

The thiazine dyes are used for dyeing paper and office supplies and also for the preparation of color lakes. The most important is Methylene Blue. In addition, the thiazine dyes have important photochemical applications. They are used as sensitizers in photopolymerization [245]. They are a component of a silver-free direct-positive color bleaching-out system, because they are reduced by the action of light and thereby bleach out the indigoid dyes also present [246]. A photochromic material consists of a polymer matrix, e.g., poly(vinyl acetate), a leuco phenothiazine dye, and a reducing agent. The dye is reoxidized on irradiation [247]. If the thiazine dye is bonded to a polymer chain, photo- and thermochromic polymers are obtained. The dye can be bonded to the polymer via acrylamide [248], chloromethylstyrene [249], or vinylpyridine [250]. Thiazine dyes inhibit the formation of polymer deposits in the preparation of vinyl chloride homo-, co-, and graft polymers [251]. Methylene Blue and other phenothiazine dyes are used as photoreducible dyes in galvanic cells [252]. They are also used in the leuco form as oxygen detectors for the detection of the undesired admission of air, e.g., in vacuum-packed foodstuffs [253]. Dissolved oxygen can be removed from alkaline water by treatment with leuco methylene blue [254]. Leuco dyes can also be used as anodic electrochromic materi-

als in electrochromic devices such as rearview mirrors, sun roofs, or windows [167].

The thiazine dyes have long been used for staining in medicine, bacteriology, and microscopy [255]. Besides Methylene Blue and its oxidation products Azur I and II, mixtures containing these dyes can be considered for microscopic investigations of cells, e.g., the mixture Methylene Blue – Eosine [256] or the mixture of Azur I or Azur II with Malachite Green and Fuchsine [257].

Thiazine dyes with a naphthalene ring system [258] are suitable for the differentiation of tissues in surgery and pathology, since they stain malignant tissue more strongly than normal tissue. For the diagnosis of cell samples by staining, radioactive tritium-labeled Methylene Blue can be used [259]. Thiazine dyes whose amino groups are replaced by haloalkyl groups have antimitotic activity [260].

4.1. Diaminophenothiazine Dyes

The reaction sequence that leads to the diaminophenothiazine dyes is described in Chapter 1. The most important dye, *Methylene Blue* **45**, C.I. 52 015 [*61-73-4*], is obtained by oxidation of 4-aminodimethylaniline in the presence of sodium thiosulfate to give the quinonediiminothiosulfonic acid, reaction with dimethylaniline, oxidation to the indamine, and cyclization to give the thiazine. The dye is commercially available as the hydrochloride and as the zinc chloride double salt.

67

Preparation. To prepare the *nitroso compound*, 150 kg of dimethylaniline, 750 kg of ice, and 183 kg of sulfuric acid (78 %) are placed in a 4000 L brick-lined kettle equipped with a wooden strirrer, and the mixture is diluted with ice water to a volume of 1600 L. Then, 215 kg of 40 % sodium nitrite solution, together with 260 L of 25 % common salt solution, is allowed to flow in over 6 h at a temperature no higher than 0 °C. The mixture is subsequently stirred for 1 h and an additional 131 L of 78 % sulfuric acid is added. For the *reduction*, the charge is placed in a 2000 L kettle equipped with a heating jacket and treated at 25 – 40 °C with 1300 kg of iron filings added in 4 – 5 portions. After filtration, the solution is placed in a wooden vat having a capacity of 16 000 L.

For the *oxidation* to the quinonediiminothiosulfonic acid, the solution is first cooled to −1 °C and then 122 kg of 78 % sulfuric acid, diluted to 600 L with water, is added in 4 portions over 50 min as well as 120 kg of sodium dichromate dissolved in water (800 L solution) and 660 kg of 45 % sodium thiosulfate solution. The final temperature should be +1 °C. Then the mixture is stirred for 1 h and the temperature allowed to rise to 3 °C. For the conversion to the *indamine*, 700 L of an aqueous solution containing 255 kg of sodium dichromate is added at 3 – 4 °C, followed by 130 kg of dimethylaniline dissolved in 125 kg of 78 % sulfuric acid and 200 L of water. After 30 min, 68 kg of sodium dichromate, dissolved in 200 L of water and ice, is added again. Finally, the mixture is stirred for 45 min.

For the thiazine-ring *cyclization*, the reaction mixture is placed in a wooden vat having a capacity of 26 m^3. Then, 36 kg of sodium dichromate, dissolved in 24 L of water, and 18 kg of copper sulfate, dissolved in 100 L of water, are added, and the mixture is heated over 30 min to 90 – 92 °C by blowing in steam. Dye formation starts between 65 and 70 °C. Finally, the mixture is stirred for another 30 min at 90 – 92 °C, and the chromium sediment is then filtered off.

To prepare the *zinc chloride double salt*, the solution is treated at 45 °C with 40 L of 30 % hydrochloric acid, 300 L of 40 % zinc chloride solution, and 1000 kg of common salt solution, saturated at 45 °C. The mixture is allowed to cool to 20 °C and the product is filtered off and dried at 60 – 65 °C in a circulating-air dryer. Yield: 375 kg.

To isolate *Methylene Blue hydrochloride*, 40 L of 30 % hydrochloric acid and 2000 kg of saturated common salt solution are added to the dye solution after it has cooled to 45 °C, and the mixture is allowed to cool further to 25 °C. After filtration, the product is washed with a 2 % common salt solution.

Instead of sodium dichromate, manganese dioxide and catalytic amounts of copper sulfate

can be used for the oxidation [261]. Finally another procedure for the preparation of phenothiazine dyes has been reported in which the reaction is carried out with sodium thiosulfate in the presence of zinc chloride and aluminum sulfate, and the oxidation is carried out with sodium dichromate in the presence of copper sulfate in sulfuric acid [262].

Highly pure Methylene Blue can be obtained by extraction of impurities with chloroform from solutions of raw dye in borate puffer at pH 9.5 – 10 followed by acidification of the aqueous solution and isolation of the dye [263].

Methylene Blue is mainly used to dye paper and office supplies, but also to tone up silk colors. In addition, it is of some importance as a chemotherapeutic agent in human and animal medicine, as a stain in microscopy, as a hydrogen acceptor in enzymatic dehydrogenations, as a redox indicator in iodometry and titanometry, and as a cosmetic dye.

It was offered as *Leather Pure Blue HB* [*61-73-4*] (Hoechst) for dyeing leather and is a mixture component in Basic Leather Black brands. Methylene Blue can be adsorbed by active charcoal and then be used to remove BF_4^- anions from wastewater [264].

Methylene Blue has also been investigated as a dye in laser technology [41] and as an IR sensitizer generating $^1O_2$ useful in holographic registration material using the polymerization of acrylic monomers [265]. It sensibilizes the photochemical degradation of azo dyes with $^1O_2$ [266]. It is used as antidote against methemoglobin-forming poisons and as disinfectant in animal medicine.

10-Benzoylleucomethylene Blue [*1249-97-4*] **46** is obtained by reduction of Methylene Blue with hydrosulfite in aqueous alkaline medium, followed by benzoylation and then extraction of the crude product with toluene [267].

68

In place of the benzoyl group, the residues of halobenzoic acids [268], nitrobenzoic acids [269], aminobenzoic acids [270], sulfobenzoic acids [271], benzenedicarboxylic acids [272], naphthalenecarboxylic acids [273], isobutyric acid [274], as well as alkyl- and arylsulfonic acids [275] have been suggested. Reaction products with esters of chloroformic acid and isocyanates [276] can also be used. The lightfastness of the printing is improved by heteropolyacids of hexavalent molybdenum, such as phosphomolybdic acid [277].

Benzoylleucomethylene blue was used as a color-forming agent in colorless copying paper [278]. It is also recommended for documents to make them safe against forgery [279].

On contact with acid substances, such as attapulgite, montmorillonite, kaolinite, or bentonite, the color of Methylene Blue is slowly developed. The compound is also used as color-forming agent in thermoreactive paper in combination with aromatic hydroxy compounds serving as acidic substances in this case. The color reaction is effected by the action of heat, which causes the melting of the covering poly(vinyl alcohol) [280].

The mechanism of color-forming decomposition of *N*-benzoylleucomethylene blue during the copying process has been studied; the reaction is induced by photons and proceeds via free radicals [281].

Benzoylleucomethylene blue was also used in combination with other chromogenic compounds, e.g., with Crystal Violet lactone [282], rhodamineanilinolactam [283], spiro compounds [284], and fluoranes [285]. Its slow development compensates the bleaching of color formers with low lightfastness, e.g., Crystal Violet lactone. *N*-Alkyl- or arylsulfonylleucomethylene blue can be used in a dye sublimation sheet which uses nickel salicylates as developing agent on the receiver sheet [286].

A commercial product of this series was *React Blue G* (BASF).

Recording materials for electron beams contain benzoyl- or naphthoylleucomethylene blue in order to increase the sensitivity [287]. Electrochromic printing media contain *N*-benzoylleucomethylene blue and a bromide, which catalyzes the electrochemical oxidation of the leuco compound [271, 288]. Benzoyl leuco derivatives of Azur I bearing an additional benzoyl group on the methylamino group can also be used in the same manner [289]. *N*-

Acylated leucophenothiazine compounds also serve to stabilize polymeric hydrocarbons [290] and polychloroprenes [291].

Leucomethylene blue is used in oxygen detectors checking, e.g., nitrogen-blanketed or vacuum-packed perishable foodstuffs [292]. It is also recommended as oxygen-sensitive reactive material in optical data storage media such as CDs and DVDs which are intended to be usable (readable) only for a limited period of time [293].

The halogenation of Methylene Blue improves the lightfastness of the color on polyacrylonitrile [294]. The selenium analogue of Methylene Blue, prepared with ^{75}Se, is used for the imaging of epithelial corpuscle adomenas [295]. Inclusion complexation of Methylene Blue in β-cyclodextrin enhances the lightfastness even on textile fibers [296] and the fluorescence intensity by a factor of 3 – 5 [297].

Derivatives of Methylene Blue bearing, instead of one methyl group, a substituent which can react with amino, thiol, or carboxyl groups are applicable to photodynamic therapy of cancer or immunoassays utilizing chemoluminescence [298].

Methylene Blue NNX, *New Methylene Blue*, C.I. 52 030 [*6586-05-6*] (Cassella, 1881), is redder and somewhat faster to light than Methylene Blue [299]. It can be prepared analogously to Methylene Blue, starting from *N*-ethyl-2,5-diaminotoluene and *N*-ethyl-*o*-toluidine, and is suitable as a stain for microscopy.

Toluidine Blue O **47**, C.I. 52 040 [*6586-04-5*] (MLB, BASF, 1888), is prepared from *N*,*N*-dimethyl-*p*-phenylenediamine and *o*-toluidine and is used as a stain for microscopy [300].

69

Methylene Green **48**, C.I. 52 020 [*6722-15-2*] (MLB, 1886), is obtained by action of nitric acid on Methylene Blue.

70

Several dyes that are important in microscopy are obtained by partial oxidative degradation of Methylene Blue, which removes some of the methyl groups. Cleavage of one methyl group gives Azur I (Azur B), of two methyl groups Azur A, and of three methyl groups Azur C. The oxidation is favorably carried out in an aqueous solution of potassium or sodium dichromate at 70 °C [301]. Highly purified rhodanides of these dyes can be made starting from the zinc chloride salts via the perchlorates [302]. Another dye for this purpose is Thionine or Lauth's Violet, C.I. 52 000 [*581-64-6*], with completely unsubstituted amino groups. A rapid method for separation and identification of these dyes is high-performance thin-layer chromatography [303].

Thiocarmin R [*6379-04-0*] (**49**; Cassella, 1890), is an acid wool dye from the series of diaminophenothiazine dyes [304]. It has been prepared, analogously to Lauth's Violet, by oxidation of 4-amino-*N*-ethyl-*N*-benzylaniline-3′-sulfonic acid in the presence of hydrogen sulfide and zinc chloride. In this case, too, better yields are obtained by using the thiosulfate method (see the discussion under Methylene Blue). According to the same preparation route, the thioninedisulfonic acid is obtained from 2,5-diaminobenzenesulfonic acid and 2-aminobenzenesulfonic acid.

71

This dye [305] as well as cationic phenothiazine dyes can be used in photogalvanic cells [306].

4.2. Aminohydroxyphenothiazine Dyes

These dyes are essentially completely present in the phenazone form (**1**, where D^2 is =O). They are suitable for dyeing polypropylene textile materials [307]. By the introduction of a second hydroxyl group in the position neighboring the auxochromic OH group, the dyes acquire the ability to form color lakes.

Brilliant Alizarin Blue G **50** and R **50**, C.I. 52 055 [*6379-01-7*] and C.I. 52 060 [6379-02-8], dye chrome-mordanted wool green-tinged

and red-tinged blue, respectively. The dyes are obtained by reaction of the corresponding phenylenediaminothiosulfonic acids with 1,2-naphthoquinone-4-sulfonic acid and -4,6-disulfonic acid, respectively (Bayer, 1892) [308].

72

73

By reaction of 1,4-naphthoquinone with thiourea, cyclic thiocarbonate **51** is obtained, which can be treated with nitrosodiethylaniline to give thiophenoxazone dye **51**. The dye is also formed in a chromogenic developing process on image-forming irradiation of dialkyl-*p*-phenylenediamine in a silver-halide-containing gelatin layer [309].

74

75

As a laser dye, it is tunable in the 660 – 700 nm range [310].

4.3. Hydroxyphenothiazine Dyes

Hydroxyphenothiazine dyes serve as starting material for sulfur dyes. 1,3,4-Trichloro-7-methylphenothiazine-2-one, obtained from chloranil and 1-methyl-4-amino-3-thiophenol, is the precursor for the former Immedial Reddish Brown CL3R.

5. Bisazine Dyes

By doubling of the general formula **1** of the azine dyes, one arrives at the general formula **52** of the bisazine dyes.

76

Whereas an uneven number of carbon atoms and heteroatoms is found between the two auxochrome groups D^1 and D^2 in the simple azine dyes, so that resonance formulas **1** – **1** are possible, the D groups in the bisazine dyes are separated by an even number of atoms, and therefore resonance in the sense of formula **1** is impossible.

The color of the bisazine dyes results from coupling of two trimethine chromophores according to **53**, which is a kind of a 1,4-didonor 2,5-diacceptor substituted benzene **53**. The mixing of their highest occupied and lowest unoccupied molecular orbitals, respectively, yields a significant bathochromic shift of the absorption band [311]. This shift and the color strength are increased by the condensed rings. Therefore, the groups D are not necessarily required and are lacking in a large number of important dyes.

77

78

The bisazine dyes include the fluorindine dyes, the dioxazine dyes, and the dithiazine dyes. Of these, the dioxazine dyes have the greatest industrial importance.

5.1. Fluorindine Dyes

Fluorindine dyes are obtained by reaction of benzoquinone derivatives with phenylenediamine. 5,12-Dialkylfluorindines can be prepared by first adding two equivalents of *N*-alkyl-*o*-phenylenediamine to benzoquinone in the cold and then heating in acidic medium to form the azine ring [312]. The compounds are also obtained by condensing 2,5-dihydroxybenzoquinone with *N*-alkyl-*o*-phenylenediamines in pyridine at reflux temperature. The dyes are suitable for polyacrylonitrile [313]. They are quaternized by the action of alkylating agents to dyes like **54**, thereby becoming more soluble and electronically more similar to monoaminophenazine dyes. Polyacrylonitrile is dyed in blue tints [314].

79

The alkylated diphenylfluorindines are also suitable for dyeing polyacrylonitrile [315]. Interesting derivatives of diphenylfluorindine are described in [316]. They are formed when 3-aminopyrenes are incorporated into azophenine compounds, and these are converted into fluorindines and made water-soluble by sulfonation. The products of high color strength dye cotton from a neutral bath in lightfast green tints. Fluorindine dyes that contain sulfo groups are obtained by reaction of *o*-phenylenediaminemono- or *o*-phenylenediaminedisulfonic acids with 2,5-dimethoxy-1,4-benzoquinone [317]. A violet pigment can be prepared by treating monobenzoyl-*o*-phenylenediamine with chloranil, followed by condensation to give the fluorindine [318].

5.2. Dioxazine Dyes

This class of dyes, which is especially important in dyeing cotton and as pigments, is prepared by reaction of benzoquinone derivatives, in particular tetrachlorobenzoquinone (chloranil), with aromatic amines. The components are first condensed in the presence of acid-binding agents to give 2,5-diarylamino-3,6-dichloro-1,4-benzoquinone. The cyclization is then carried out under oxidative conditions in high-boiling solvents in the presence of aromatic acid chlorides or in concentrated sulfuric acid [319]:

80

Instead of the widely used *o*-dichlorobenzene aryl alkyl ethers are recommended as halogen-free solvents [320].

Several modifications of the cyclization step allow the reaction to be run under milder conditions, even at room temperature: oleum [321], manganese dioxide in sulfuric acid [322], chlorine in oleum [323], iodine or an inorganic [324] or organic [325] iodine compound in oleum, bis(acetoxyiodo)benzene [326], perborate or percarbonate in sulfuric acid or oleum [327], electrochemical oxidation [328].

If the aromatic rings A and B do not contain, e.g., a sulfo group compounds **56** are water-insoluble and have pigment character. Of special importance is *Pigment Violet 23* **56**, C.I. 51 319 [*6358-30-1*], formed by condensation of chloranil with 3-amino-*N*-ethylcarbazole. Linear structure **56** was believed for long time to be the right one. But three-dimensional X-ray diffraction analysis revealed the angled structure **56** [329].

81

81a

Linear structure **56** is said to exhibit a blue shade and very poor application properties compared with the angled structure **56**.

Starting from 3-amino-2-methoxycarbazoles dioxazines having a linear **56** or angular **57** structure seem to be obtainable depending from the conditions used for the ring closing step, whereby the methoxyl groups are split off (→**56**) or retained in the molecule (→**57**) [330]. With such carbazoles bearing a long-chain alkyl group on the nitrogen atom, soluble carbazoledioxazine dyes have been synthesized by condensation with chloroanil and ring closure in 1-chloronaphthaline at 220 °C. The linear structure (analogous to **56**) of the molecule has been confirmed by ^{1}H NMR spectroscopy and X-ray crystallography [331]. Such long-chain substituted dyes are recommended as colorants in resins, inks, and for photoelectric materials [332].

82

The preparation of Pigment Violet 23 is described below. The pigment serves for the dyeing of plastics, such as PVC, polyolefins, polystyrene, and rubber, as well for the preparation of printing colors and paints. It is also recommended for use in electrophotography [333], in organic electroluminescence devices [334], for optical data storage [335], or as shading agent together with copper phthalocyanine as light filter in liquid crystal displays [336]. To convert the crude dye to a clear, color-strength pigment, the aqueous suspension is heated in the presence of an aliphatic or alicyclic alcohol [337], an aromatic hydrocarbon [338], a ketone, or an acetic ester [339]. The pigment can be dispersed by dissolving it in a haloacetic acid and diluting it with water or a water-miscible solvent [340]. Dispersion can also be achieved by grinding in a vibrator mill [341]. The dispersability of the pigment can be improved by mixing it with a derivative of this pigment bearing amino or heterocyclic groups bound to the chromophore by spacer groups such as methylene or sulfonyl [342]. Mixtures with derivatives obtained by reaction of Pigment Violet 23 with chlorosulfonic acid followed by reaction with dimethylaminopropyleneamine result in paint or ink dispersions with low viscosity and high gloss [343].

Pigment Violet 23 as tailor-made preparations for different applications is commercially available in a great variety of assortments, e.g., *Hostaperm Violet BL*, *Hostatint Violet RL*, *Colanyl Violet RL 200* (Clariant), *Paliogen Violet L 5890*, *Xfast Violet ED 7575* (BASF), *Pigment Violet 23* (Sun-Chemicals).

The halogen-free pigment is also known. It is synthesized from *p*-benzoquinone and 3-amino-*N*-alkylcarbazoles under oxidative conditions [344] or from 2,5-dihalo- [345] or 2,5-dihydroxy-1,4-benzoquinone [346]. The monochloro pigment is analogously obtained from 2,3,5-trichloro-1,4-benzoquinone [347].

Water-soluble dyes are formed by sulfonation. They dye cotton directly in vivid violet and blue tints and are characterized by high lightfastness and high color strength. Because animal fibers are also deeply colored, the sulfonated dioxazine dyes are suitable in mixture with acid wool dyes for the dyeing of half-wool. These industrially important dyes are derived from 4-aminodiphenylamine or from multinuclear aromatic amines.

Sirius Light Blue FFRL, or *Remastral Blue FFRRL*, C.I. 51 320 [*1324-58-9*], is prepared by condensation of chloranil and 3-amino-*N*-ethylcarbazole followed by sulfonation [319].

Preparation. 1) *Condensation and oxazine-ring cyclization*. In a 2000 L enamelled kettle equipped with heater, stirrer, and condenser, 100 kg of 3-amino-*N*-ethylcarbazole, 42.5 kg of water-free sodium acetate, and 87.5 kg of chloranil are mixed by stirring in 1940 kg of *o*-dichlorbenzene at 50 – 55 °C. The mixture is stirred for 2 h at 60 – 68 °C, and the acetic acid is then distilled under vacuum at 115 °C. Subsequently, 45 kg of benzenesulfonyl chloride is added at 150 °C, and the solution is heated to 175 – 180 °C, stirred for 4 h at this temperature, allowed to cool, diluted with *o*-dichlorobenzene, and filtered at 100 °C through a pressure filter. The filter residue is washed with *o*-dichlorobenzene at 100 °C until a sample amount, boiled in *o*-dichlorobenzene, fluoresces red rather than blue. The *o*-dichlorobenzene is then removed by steam distillation and the product is washed with hot water and dried at 100 °C.

2) *Sulfonation*. 85 kg of ground dioxazine intermediate is added through a sieve over 2 h at room temperature to a mixture containing 1050 kg of 95.5 % sulfuric acid and 1050 kg of fuming sulfuric acid (29 % SO_3). The mixture is heated to 90 – 95 °C over 1 h and stirred for 8 h at this temperature. It is then allowed to cool to 25 – 30 °C. 1000 kg of water and 2000 kg of ice are added, the mixture is stirred for 24 h and filtered, and the product is washed with a 17 % solution of NaCl. The sulfonated product is mixed with 1000 kg of a 23 % solution of NaCl and made weakly alkaline with a solution of soda. After 2 h of stirring, the sodium salt is salted out with 100 kg of NaCl, filtered, and washed with 1500 L of a 23 % NaCl solution until the filtrate flows out with a weak blue color. The salt is dried at 60 – 70 °C.

The reaction of chloranil with 3-amino-*N*-ethylcarbazole is favorably carried out in the presence of a phase-transfer catalyst, e.g., tetrabutylammonium chloride [348]. Organic bases such as triethylamine, piperazine, and pyridine have also been suggested as acid-binding agents [349]. Benzenesulfonic acid and toluenesulfonic acid are also suitable as condensation agents [350]. Heterocyclic *N*-oxides such as 4-picoline *N*-oxide are advantageous because they produce less wastewater than arenesulfonyl chlorides, but high yields of pigments [351].

The unsulfonated color bases can be treated with *N*-hydroxymethylchloroacetamide to add one to four amidomethyl groups to the dye molecule. With pyridine, the chlorine substituent is exchanged for the pyridinium group to give cationic dyes that are suitable for spin dyeing of polyacrylonitrile [352]. By the action of oleum on these dyes, compounds are formed that bear cationic charges as well as sulfo groups and are suitable for dyeing natural and synthetic fibers as well as paper and leather [353]. The chloroacetyl group can also be cleaved off with hydrochloric acid and the aminomethylated dye can be treated with the reaction product formed from cyanuric fluoride and *o*-sulfanilic acid. The dye thus obtained reacts with natural and regenerated cellulose with formation of a covalent bond [354].

Sirius Light Blue FF2GL, or *Remastral Blue FF2GL* **58**, C.I. 51 300 [*6527-70-4*], is prepared from chloranil and 4-aminodiphenylamine-2-sulfonic acid [355].

83

Other trade names were, *Solophenyl Brilliant Blue BL*, *Chlorantin Fast Brilliant Blue 2 GL* (Ciba-Geigy), *Tertro Direct Light Blue 2GLN* (Crompton & Knowles).

The corresponding dye obtained from 4-amino-4′-chlorodiphenylamine-2-sulfonic acid is *Sirius Light Blue FFB*. These dyes are also suitable for the batch dyeing of polyamides [356].

The reaction of chloranil with 1,4-phenylenediamine-2-sulfonic acid gives, after cyclization, a dioxazine dye with primary amino groups which dyes polyamide a clear blue [357]. By reaction with cyanuric chloride, it is converted to a reactive dye [358]. Introduction of substituted amino groups into the triazine rings gives dyes useful as direct dyes for textile fibers, leather, paper, and in ink-jet inks [359]. Two chromophores of this dioxazine dye can be combined by a bridging group formed by reaction with, e.g., phosgene or dicarboxylic acid dichlorides [360] or cyanuric chloride [361]. These dyes give a brilliant lightfast blue tint on cellulosic mate-

rial such as cotton and paper. They are also recommended as dichroitic dyes in light-polarizing films [362].

A sulfone residue can be introduced into these dyes in *ortho* position to one of the amino groups by reaction with sulfinic acids, e.g., acetamidobenzenesulfinic acid, in the presence of an oxidizing agent, e.g., potassium peroxodisulfate [363]. These dyes provide brilliant reddish blue shades on polyamide and wool.

Another starting material for the preparation of dioxazine reactive dyes is the product obtained from the reaction of 4,4′-diaminodiphenylamine disulfonic acid with chloranil. The primary amino groups react with cyanuric chloride to form **59** [364] (see first scheme on bottom of this page).

Another reactive group can be introduced into this dye by allowing the second chlorine atom of cyanuric chloride to react with the sulfate ester of 3-aminophenylhydroxyethylsulfone [365]. Commercial products of this series were *Procion Blue MX-G* [*72847-56-4*] (ICI), *Intracron Blue C-G* (Crompton & Knowles).

Dyes of this type in which rodlike substituents are fixed to the amino groups can be used as dichroitic dyes in polarizing films. They show excellent durability especially to heat and under moist, hot conditions [366].

Asymmetrical dioxazine dyes can be synthesized by subsequent condensation of chloranil with *p*-phenylenesulfonic acid and *p*-phenylene-2,6-disulfonic acid followed by ring closure. Reaction with cyanuric chloride and substitution of the remaining two chlorine atoms by metanilic acid and 2-(2′-hydroxyethylsulfonyl)ethylamine yields a reddish blue dye, which after esterification of the free hydroxyl group by 100 % sulfuric acid becomes a reactive dye, especially for cellulose fiber materials [367] (see second scheme on bottom of this page).

Dioxazine dyes that bear an aminoalkylamino group are starting materials for the preparation of reactive dyes such as **61**. The aliphatic amino group is reacted with cyanuric chloride [368] or with cyanuric fluoride [369], a second halogen atom on the triazine ring usually being exchanged for an anilinesulfonic acid. Higher brilliance, a less reddish blue shade, and a higher stability to alkali are said to be the advantages of these chromophores (see last scheme on bottom of this page).

Substitution of the third halogen atom by an amine [370] or by nicotinic acid [371] results in paper dyes and reactive dyes for cotton, re-

84

85

86

spectively, which can be used under neutral to acidic dyeing conditions [372]. *Procion Blue H-EG*, C.I. 51 307 [*77093-21-1*] (ICI, DyStar), *Kayacelon React Brilliant Blue CN-FL* (Nippon Kayaku) is a commercial dye of the latter type.

Oligomeric dyes can be synthesized by reaction of these aminoalkylamino groups with bifunctional acid chlorides, e.g., terephthalic acid dichloride [373]. These dyes can be used for dyeing and printing of cellulose material.

The precursors of these dyes can be desulfonated by heating in the presence of a mineral acid and subsequently alkylated. The cationic dyes thus obtained are suitable for dyeing paper [374]. Starting from γ-[2-(β-hydroxyethylsulfonyl)-4-aminoanilino]propyltrialkylammonium iodide, e.g., reaction with chloranil, ring closure, and esterification of the hydroxyl groups yields a cationic reactive dioxazine dye of high color strength which dyes cellulose, wool, or polyamide in fast reddish blue hues [375].

Red dioxazine dyes are obtained by condensation of 4-aminodiphenyl ether with chloranil, followed by either sulfonation of the dioxazine to give a polyamide dye [376] or by reaction of the dioxazine with *N*-hydroxymethylchloroacetamide and pyridine to give a cationic paper dye such as **62** [377].

87

Condensation of chloranil with 3-sulfo-4-(ω-acylaminoalkoxy)anilines followed by hydrolysis of the amide and reaction with a fiber-reactive group, e.g., with cyanuric fluoride and than with anilinesulfonic acid [378], or condensation of chloranil with 3-sulfo-4-(ω-sulfatoethylsulfonylalkoxy)anilines [379] yields bluish red dyes for reactive dyeing of cellulose material. Chlorine-free magenta dyes useful for inkjet printing are synthesized from tetraphenoxybenzoquinone, obtained from chloranil and phenol, and 4-ethoxyaniline-3-sulfonic acid [380]. *Sirius Light Blue F3GL*, or *Remastral Blue F3GL* **63**, C.I. 51 310 [*30282-46-3*], is obtained by condensation of chloranil with aminopyrene and cyclization in the presence of *p*-toluenesulfonyl chloride and 1-chloronaphthalene at 260 °C. Sulfonation is carried out with a 15-fold excess of sulfuric acid monohydrate at 20 °C for 36 – 40 h [381].

88

Sirius Light Violet FRL, or *Remastral Violet FRL*, C.I. 51 325 [*1324-43-2*], is obtained correspondingly from 2-aminofluorene [382].

If aromatic amines that bear an alkoxyl group in the position neighboring the amino group are used for the condensation, the oxazine-ring cyclization takes place with elimination of alcohol. Pigment dyes are obtained by condensation of chloranil with 1,4-dialkoxy-2-amino-5-aroylaminobenzenes followed by ring cyclization in concentrated sulfuric acid [383] with reacylation of saponified acylamino groups [384] or by ring cyclization in a solvent in the presence of sodium sulfate [385].

Commercial products of this class of dyes were *Irgazin Violet BLT* [*55177-94-1*] and *6RLT* [*12612-32-7*] (Ciba-Geigy).

Pigment dyes that bear acylamino groups instead of chlorine in the 3- and 6-positions are obtained by reaction of 2,5-dihalo-3,6-bis(acylamino)-1,4-benzoquinone with aromatic amines bearing an alkoxyl group in the position neighboring the amino group. Suitable acyl groups are the benzoyl group [386], the acetyl group [387], and the thiophenoyl group [388]. By exchange of the halogen atoms in the 3- and 6-positions for the cyano group, other valuable pigment dyes can be prepared [389]. Phenoxyl groups [390], carboxylic es-

ters, or carbonamide groups [391] also come into consideration as substituents in the 3- and 6-positions.

A commercial product of this series is *Cromophtal Violet B* [*57971-98-9*] (Ciba).

6-Sulfonyl-substituted dioxazine dyes with alkyl or aryl groups in the 3-position are recommended for dyeing paper or cotton as substantive [392] or reactive dyes [393].

Dioxazine dyes that bear alkoxyl groups [394], polyether groups [395], or phenoxyl groups [396] as substituents are suitable for the spin dyeing of polyesters. A color-strong, reddish violet vat dye is reported to be formed by treatment of triphendioxazine with $AlCl_3 \cdot 2 S_2Cl_2$ complex [397].

Dioxazine dyes, e.g., Pigment Violet 23, are suitable for information storage using the gallium arsenide semiconductor laser due to their absorption between 600 and 800 nm [398].

Musso et al. have investigated the formation of triphendioxazine from 2-hydroxy-*p*-benzoquinone and 2-aminophenol [399].

5.3. Dithiazine Dyes

Dithiazine dyes are suitable in their sulfonated form for the substantive dyeing of cotton [400]. To prepare the parent substances (**64** or **65**), two methods can be considered: the sulfurization of *N*,*N′*-diarylphenylenediamines and the reaction of phenothiazones with *o*-aminothiophenols. *N*,*N′*-diarylphenylenediamines are obtained by reaction of hydroquinone with aromatic amino compounds in the presence of sulfanilic acid at 240 °C.

Preparation. In a typical sulfurization, 52 g of *N*,*N′*-diphenyl-*p*-phenylenediamine is heated with 14.6 g of sulfur and 0.15 g of iodine for 4 h in a stream of air at 180 °C. The cold product is pulverized and extracted by boiling with 1 L of toluene. The violet dithiazine is extracted from the residue with 1,2-dichlorobenzene or pyridine.

89

The reaction of phenothiazones with *o*-aminothiophenols proceeds according to the following equation:

90

The diazine dyes thus obtained are sulfonated at 60 °C with sulfuric acid or oleum, depending on their constitution. The sulfonic acids dye cotton with reddish-violet to green tints.

Aziridines are three-membered organic heterocycles which contain one nitrogen atom in the ring. All commercially available aziridine derivatives are made from ethylenimine (aziridine) and propylenimine (2-methylaziridine). Aziridines can undergo polymerization reactions, i.e., homopolymerization to form polyethyleneimines, or graft and copolymerization reactions to give aziridine-modified polymers. Polyfunctional aziridines are obtained by reaction of ethylenimine and propyleneimine and trifunctional arcylates. Ethylenimine and propylenime react with thiols and amines in ring-opening reactions, with oxiranes and isocyanates under preservation of the aziridine ring.Ethylenimine is produced industrially by the β-chloroethylamine process, the Dow process, the Wenker process and the catalytic 2-aminoethanol dehydration process. Aziridines, polyethylenimines and aziridine-modified polymers are used primarily in the coatings, paper, water treatment, textile, and petroleum industries. Aziridines are highly toxic. Their toxicity probably results from alteration of nucleic acids, proteins, and other important biochemicals by alkylation. Substances derived from aziridines but no longer containing the aziridine ring, e.g., polyethyleneimines, are normally of low toxicity.

1. Introduction

Aziridines are saturated three-membered ring compounds containing a single nitrogen atom in the ring. All commercially available aziridines and aziridine derivatives are made from ethylenimine (**1**) or propylenimine (**2**). Ethylenimine is also called aziridine [*151-56-4*] and propylenimine is called 2-methylaziridine [*75-55-8*].

1

2

Ethylenimine was first prepared in 1888 by Gabriel [4], who mistakenly called it vinylamine. He prepared the ethylenimine by reacting 2-bromoethylamine hydrobromide [*2576-47-8*] with silver oxide [*1301-96-8*] or potassium hydroxide [*1310-58-3*]. Propylenimine was first prepared in 1890 by Hirsch [5] from 2-bromopropylamine [*20888-43-1*] in a similar manner. Commercial production of ethylenimine was launched in Germany in 1938.

2. Physical Properties

Ethylenimine and propylenimine are clear, colorless liquids with amine-like odors. They are

© 2007 Wiley-VCH Verlag GmbH & Co. KGaA, Weinheim
10.1002/14356007.a03_239.pub2

miscible with water and most organic liquids. Pure aziridines are generally stored over solid sodium hydroxide [*1310-73-2*] and when stored in this manner are stable indefinitely. Other properties are shown in Table 1.

Table 1. Physical properties

	Ethylenimine	Propylenimine
M_r	43.07	57.10
Density at 25 °C, g/mL	0.832	0.802
bp, °C	57	66
mp, °C	−74	−65
Vapor pressure, 25 °C, kPa	28.5	18.7
Refractive index n_D^{25}	1.4123	1.4084
Viscosity, 25 °C, mPa · s	0.418	0.491
Flash point (closed cup), °C	−11	−4

3. Chemical Properties

Ethylenimine and propylenimine are highly reactive, versatile compounds that participate in two general types of reaction: (1) the ring-preserving reactions, involving alkylation or acylation of the ring nitrogen atom, and (2) the ring-opening reactions, involving protonation of the ring nitrogen followed by nucleophilic attack at one of the carbon atoms. Use of aziridines frequently is the most economical and efficient method of incorporating an ethylamine group into a polymer or into a complex organic molecule.

3.1. Homopolymerization

Polyethylenimine [*9002-98-6*] is produced by the homopolymerization of ethylenimine [6] [7] [8]. The reaction is catalyzed by acids, Lewis acids, or haloalkanes. The polymerization is usually carried out at 90 – 110 °C in water or in a variety of organic solvents. The average molecular mass of the polyethylenimine prepared as described above is 10 000 – 20 000. Higher molecular mass polymers are prepared by addition of a difunctional alkylating agent, such as chloromethyloxirane [*106-89-8*] or 1,2-dichloroethane [*107-06-2*]. Polyethylenimines with a higher average molecular mass can also be provided by ultrafiltration of polymers with a broad mass distribution [9, 10]. Likewise, polymers of lower molecular mass can be obtained by inclusion of a low molecular mass amine, such as 1,2-ethanediamine [*107-15-3*], during polymerization [11]. By using these techniques a range of molecular masses from 300 to 10^6 can be obtained. Cross-linking during the polymerization of ethylenimine in organic solvents leads to solid polyethylenimines [12]. Furthermore the polymerization process can be conducted on the surface of organic [13] or inorganic [14] materials, thus fixing the polyethylenimines to a support.

All of these polyethylenimines are highly branched polymers having roughly a spherical shape. The amine distribution is approximately 30 % primary, 40 % secondary, and 30 % tertiary. This distribution can be readily determined by ^{13}C NMR spectroscopy [15]. By using special techniques in the polymerization of ethylenimine, more linear [16] and more branched [17] polymeric structures can be obtained. Polyethylenimines can be easily modified by polymer-analogous reactions to increase their performance in certain fields of application.

Trade names: Lupasol, Polymin, Catiofast, Lugalvan (BASF), Epomin (Nippon Shokubai).

3.2. Aziridine-Modified Polymers

Ethylenimine and propylenimine graft copolymers can be obtained by reaction of ethylenimine with polymers either having carboxyl groups attached to the polymer backbone [18, 19] or having amines in their backbone [20]. This reaction improves the adhesion of the polymer to anionic surfaces or surfaces containing hydroxyl groups.

An alternative method of introducing polyethylenimine-type side chains into other polymers is by (co-)polymerizing monomers which are functionalized by oligoethylenimine side chains [21]. By this method, carboxylic acid-free polymers with high charge densities can be obtained.

3.3. Polyfunctional Aziridines

Ethylenimine and propylenimine react with trifunctional acrylates, such as 2-ethyl-2-(hydroxymethyl)-1,3-propanediol triacrylate [*15625-89-5*] or 2,2-bis(hydroxymethyl)-1,3-propanediol triacrylate [*3524-68-3*], to produce trifunctional aziridines.

This reaction is normally carried out in the absence of solvent and does not require a catalyst. The resulting products are clear, slightly viscous liquids.

Trade names: Corial Härter AZ (BASF), Chemitite PZ (Nippon Shokubai), Xama (EIT), Crosslinker CX 100 (Zeneca), Ionac Pfaz (Sybron Chemicals). The cross-linkers are sold under their chemical names by Sogo Pharmaceutical.

3.4. Miscellaneous

Ethylenimine reacts with hydrogen sulfide to yield thiols and with thiols to give aminoethyl sulfides. This reaction is used commercially [22] to produce cysteamine (2-aminoethanethiol) (**3**) [*60-23-1*], a raw material for the synthesis of pharmaceuticals, and 2,2′-thiobisethylamine (**4**) [*871-76-1*].

3

4

The reaction of ethylenimine with 2-mercaptoethanol to give 2-[(2-aminoethyl)thio]ethanol [*24304-84-5*] (**5**), an intermediate for dye production, and with sulfurous acid to give taurine (2-aminoethanesulfonic acid) [*107-35-7*] (**6**), an essential additive for mammalian nutrition, are further examples of industrially relevant ring-opening reactions of ethylenimine with sulfur nucleophiles.

The reaction of ethylenimine with amines provides an elegant synthetic route to asymmetrically substituted ethylenediamines, e.g. *N*,*N*-dimethyl-1,2-ethanediamine (**7**) [*108-00-9*] [23].

5

6

7

Ethylenimine and propylenimine react with oxiranes, opening the oxirane ring while leaving the aziridine ring intact. For example, 1-aziridine ethanol [*1072-52-2*], 1-(2-hydroxyethyl)ethylenimine, has been produced by the

reaction between ethylenimine and oxirane [*75-21-8*].

Another commercial application of ethylenimine is the reaction with isocyanates to give iminoureas. For example, ethylenimine reacts with 1,6-diisocyanatohexane [*822-06-0*]:

4. Production

Four industrial processes for ethylenimine production have been described in the literature: the β-chloroethylamine process, the Dow process, the Wenker process (BASF) and the catalytic 2-aminoethanol dehydration process (Nippon Shokubai). Only the two last-mentioned processes are still used today. The 2006 capacity for ethylenimine monomer worldwide is estimated to be about 9 000 t/a. Because of the toxicity and high reactivity of the monomer the two major producers, BASF and Nippon Shokubai, do not sell the monomer, but directly convert it to nontoxic polymers and intermediates.

4.1. The β-Chloroethylamine Process

From 1938 till 1963, ethylenimine was produced commercially in Germany by the reaction of 2-chloroethylamine hydrochloride [*870-24-6*] with sodium hydroxide. Disadvantages of this process are, similar to the Dow Process, the corrosivity of the chloride byproduct and the risk of contamination of the ethylenimine product with β-chloroethylamine. Since β-chloroethylamine can readily eliminate HCl, which then initiates uncontrolled polymerization of ethylenimine, this contamination must be carefully avoided.

4.2. The Dow Process

In 1963 Dow Chemical began production of ethylenimine by a newly developed process that offered the possibility of significantly lower raw material costs [24]. This process is based on the reaction of 1,2-dichloroethane with excess ammonia [25]. Dow stopped production in 1978.

The advantage of this process is its low raw material cost. However, there are difficulties caused by impurities in the ethylenimine, high corrosion rates, and waste-stream disposal.

4.3. The Wenker Process

In 1935, Wenker [26] developed a process for making ethylenimine that is still the basis for most of the commercial production today. BASF produced ethylenimine according to the Wenker process in Ludwigshafen, Germany for more than 30 years safety without technical problems. The Wenker process is a two-step process, initially involving the reaction of 2-aminoethanol with sulfuric acid to give 2-aminoethyl hydrogensulfate [*926-39-6*] [27]:

The product is a water-soluble, nonvolatile solid with properties similar to those of an amino acid. This ensures, that, in contrast to the β-chloroethylamine and Dow processes, no contamination of the ethylenimine occurs. The 2-aminoethyl hydrogensulfate reacts with aqueous sodium hydroxide to produce ethylenimine. The cyclization is preferably carried out under pressure at elevated temperatures [28, 29].

Originally yields of only 26 % were obtained, but yields of 85 – 90 % [30] are now attained. The advantage of this process is the production

of pure ethylenimine with no significant waste-disposal problems. The disadvantage is the relatively high raw material cost.

4.4. Catalytic 2-Aminoethanol Dehydration Process

Numerous attempts have been made to establish a direct industrial synthesis for ethylenimine starting from 2-aminoethanol [*141-43-5*] since the 1970s [31]. The key to an economic process was a suitable catalyst, which took a long time to develop. In 1990, Nippon Shokubai eventually started an industrial ethylenimine production via catalytic dehydration of 2-aminoethanol. The reaction is carried out at 350 – 450 °C, preferably under reduced pressure with a catalyst which has weakly acidic and weakly basic centers, e.g., SiO_2 doped with barium, cesium, and phosphorus. In this gas-phase reaction, selectivities up to 90 % at conversions from 40 – 80 % can be obtained. Unconverted 2-aminoethanol is recycled from the product mixture and used as feedstock [32 – 35].

The advantage of the gas-phase process over other industrial processes is that it is a salt-free direct one-step synthesis based on 2-aminoethanol. Disadvantages are:

- Multistage distillation is required for the separation of ethylenimine from byproducts and for the recycling of 2-aminoethanol
- High energy demand
- Necessity for repeated regeneration of the catalyst due to deposition of coke and loss of phosphorus compounds [36]

5. Environmental Protection

The primary environmental concern is the prevention of aziridine vapors from entering the environment (see Chap. 8). Efficient scrubbers should be used on any vent line or hood exhaust where aziridine vapor may be present. An effective scrubbing medium is an aqueous solution of diammonium thiosulfate [*7783-18-8*].

The only waste stream from the Wenker process is an aqueous one, primarily containing sodium sulfate [*15124-09-1*] along with small amounts of various organic nitrogen compounds. This stream can be used by a kraft pulp mill as a source of sulfate, making the Wenker process essentially a non-waste-producing system. No waste streams are produced in the preparations of the principal aziridine derivatives, i.e., homopolymer, aziridine-modified polymers, and polyfunctional aziridines.

6. Uses

Aziridines are used primarily to manufacture products for the coatings, paper, water treatment, and petroleum industries.

In the *coatings* industry, polyfunctional aziridines are used to cross-link polymers with pendant carboxyl groups. These cross-linked polymers are used in a variety of performance coatings, such as those on exterior wood panels. Polyethylenimines are used as tie-coat adhesives, e.g., in the production of polypropylene laminated films [37], as adhesion promoters, and as pigment dispersants. Furthermore, polyethylenimines are excellent primers, e.g., for acrylate-based adhesives, and are used as amine components in epoxy and polyurethane resins.

In the manufacture of *paper*, polyethylenimine and aziridine-modified polymers are used as retention and drainage aids [38, 39]. Due to increasing rates of paper recycling and the trend towards closed water circuits in the paper industry, the role of polyethylenimines as fixing agents for soluble and insoluble contaminants (stickies) has gained importance [40].

Polyethylenimines are used in *water treatment* as clarifying aids [41] and are effective silica antiscaling agents [42]. Polyethylenimines can be used as *chelating agents* for heavy metal ions such as copper, rhodium, mercury and zinc. By carboxymethylation the complexing abilities of the polyethylenimines can be extended to other heavy metals and even alkaline earth metals. The enrichment of heavy metals from aqueous solutions can be conducted by membrane technology with polyethylenimine solutions [43, 44] or with solid polyethylenimines.

They are also used in the manufacture of *reverse osmosis membranes* [45].

In *textile* applications, polyethylenimines can be used in dyeing pretreatment and posttreatment of textiles to improve dye fixation and fastness. Furthermore, they improve the anti-static properties of hydrophobic fibers and enhance shrinkproofing [46].

Polyethylenimines also have applications in *metal surface treatment*. They are used as brightener components for galvanic baths: Zinc, tin, copper, and other metals including alloys as well as passivations and finishes [47].

In *air purification*, polyethylenimines can be used as adsorbents for acidic gases, ozone and aldehydes.

Polyethylenimines have several applications in the drilling and completion of *oil* and *gas* wells and in the subsequent production of oil. Polyethylenimines are used in conjunction with a sulfonated polymer, such as lignosulfonate or a condensed naphthalenesulfonate, to inhibit fluid loss from well cement [48]. They have also been used commercially as selective flocculants in drilling fluid and as demulsifiers for some crude oil emulsions.

An important emerging technology is the use of polyethylenimine to *immobilize enzymes* [49].

The high affinity of polyethylenimine for proteins such as hair or skin opens the door to a variety of *cosmetic and personal care applications*. For these purposes, the original high charge density of the polyethylenimines can be tuned to the desired degree by chemical modifications, e.g., alkoxylation.

Polyethylenimines can also be used as additives in *detergents* [50].

7. Economic Aspects

The cost of producing ethylenimine depends on the price of 2-aminoethanol and on the high capital requirements needed to build a safe and efficient ethylenimine plant. The cost of a plant is high because of both the highly toxic nature of the ethylenimine and the lack of gasket material that can withstand prolonged contact with ethylenimine. This means that a modern ethylenimine production facility will be almost entirely of welded construction, using gasketless pumps, valves, and flow meters. Therefore, ethylenimine is significantly more expensive to produce than monomers used in most other water-soluble polymers. The price per kilogram of polyethylenimine depends on quantity. Small quantities of polyethylenimine sold for 11 – 18 €/kg in the last few years.

Ethylenimine is produced commercially by BASF (Germany) and Nippon Shokubai Kagaku Kogyo (Japan). Propylenimine has become available from Aceto Corp./Arsynco (USA), Dixie Chemical Company (USA), and Whyte Chemicals (UK). Sybron Chemicals (USA) started up their own propylenimine plant for the production of propylenimine-based crosslinkers.

8. Toxicology and Occupational Health [51 – 54]

Like many strong alkylating agents, aziridines are highly toxic. Their toxicity probably results from alteration of nucleic acids, proteins, and other important biochemicals by alkylation.

At one time substances with two or more aziridine rings, such as triethylenemelamine (**8**) [*51-18-3*], were considered promising antineoplastic drugs.

Many were prepared, a half dozen or more went to clinical trial, and some were used to treat cancer. However, although capable of inhibiting tumors and killing cancer cells, they were found to have serious side effects. These included severe damage to lymphatic cells and bone marrow and diminished fertility. Moreover, they often proved carcinogenic in animal tests. Because of these properties, they are rarely used as antineoplastic drugs today. However, the extensive testing of these agents, added to the testing of simple, commercially important aziridines, has provided more knowledge of the toxicological properties of aziridines than is available for most chemical classes. For example, the International Agency for Research on Cancer (IARC) has reviewed carcinogenic data of eleven aziridines

Table 2. Acute toxicity, doses in mg/kg

	EI	PI	Xama-7	Corcat P-600
Acute oral (LD_{50})	14	19	2000	7500
Acute dermal (LD_{50})	13	43	>3000	>3000
Eye irritation	severe	severe	moderate, transitory	irritant

[52]. For nine the data were sufficient to classify the substances as carcinogens. Clearly, any aziridines that have not been tested should be considered potential carcinogens.

8.1. Ethylenimine

In animal studies ethylenimine is highly toxic by ingestion, inhalation, skin or eye application, and injection. For example LD_{50} (oral, rat) is 14 mg/kg; LD_{50} (skin, rabbit) is 13 mg/kg; LC_{50} (10-min inhalation, mouse) is 2236 ppm. In inhalation studies, lethal air concentrations typically cause irritation of nose and eyes during exposure, with edema and other signs of lung injury becoming evident a few hours afterwards, and death ensuing a few days later.

To humans ethylenimine is a skin sensitizer and a severe irritant to eyes, nose, and throat. Transient CNS, liver, and kidney damage has been observed. Two deaths have been reported, one from inhalation and one from skin contact.

Ethylenimine is a mutagen in microbial and fruit fly tests. It proved carcinogenic by the oral and subcutaneous route in four mouse tests. However, an epidemiological study of 144 aziridine workers found no evidence of carcinogenicity.

Ethylenimine is classified by OSHA as a "cancer suspect" agent and detailed standards and work practices are prescribed to prevent any significant exposure by inhalation, ingestion, or skin or eye contact. The ACGIH recommends a TLV of 0.5 ppm, with skin contact to be avoided [53]. The DFG classifies ethylenimine as an A 2 carcinogen and a category 2 germ cell mutagen, requiring special protective and surveillance measures [54].

8.2. Propylenimine

The toxic properties of propylenimine are similar to those of ethylenimine. Limited studies in rats suggest it is one-fourth to one-eighth as toxic by inhalation, and this is part of the basis for the TLV of 2 ppm set by the ACGIH. In oral rat studies it produced a variety of malignant tumors. It is classified an A 2 suspected carcinogen by ACGIH, an A 2 proved animal carcinogen and a category 2 germ cell mutagen by DFG. It should be handled with the same care as ethylenimine.

8.3. Aziridine Derivatives and Polyethylenimines

Substances derived from aziridines but no longer containing the aziridine ring are normally of low toxicity. Examples are polymerized aziridines and polymers that have been modified by reaction with aziridines.

Polyethylenimine is used in personal care products and in food packaging materials. Table 2 shows toxicity data for ethylenimine (EI) and for propylenimine (PI) as well as for a typical polyfunctional aziridine (Xama-7) and a typical polyethylenimine (Corcat P-600).

FDA approval as an additive for food packaging on certain substrates exists for certain polyethylenimines (PEI; Lupasol grades) under the following parts:

- 173.357: PEI for enzyme immobilization
- 175.105: PEI for food packaging
- 175.320: PEI on polyolefin in contact with food
- 176.170: PEI in paper in contact with aqueous and fatty food
- 176.180: PEI in paper in contact with dry food
- 177.1200: PEI on cellophane in contact with food

1. Introduction [1–6]

Azo dyes are characterized by a chromophoric azo group −N=N−, whose nitrogen atoms are linked respectively to sp^2-hybridized carbon atoms. At least one of these carbon atoms belongs to an aromatic carbocycle (usually a benzene or naphthalene derivative) or heterocycle (e.g., pyrazolone, thiazole), whereas the second carbon atom adjoining the azo group may also be part of an enolizable aliphatic derivative (e.g., acetoacetic acid). The most common types of azo dyes can thus be summarized as follows: aryl−N=N−R, where R can be an aryl, heteroaryl, or −CH=C(OH)−alkyl.

Due to the simple nature of the synthesis, usually in aqueous medium, and the almost unlimited choice of starting products, an extremely wide variety of azo dyes is possible. The number of combinations is further increased by the fact that a dye molecule can contain several azo groups.

This diversity of inexpensively produced azo dyes permits a wide spectrum of shades and fastness properties suitable for use on a variety of substrates.

Naturally occurring azo dyes are unknown (some containing azoxy groups are known), but the azo dyes represent the most numerous and widely manufactured synthetic dyes.

Nomenclature. Depending on the number of azo groups, the azo dyes are called monoazo, disazo, trisazo, tetrakisazo, etc., dyes, and those with three or more azo groups, polyazo dyes.

The structure of an azo dye can be described by means of a structural formula (a), IUPAC nomenclature (b), or practical nomenclature (c), e.g.:

a)

b) 1-hydroxy-2-phenylazo-7-(4′-nitrophenylazo)-8-aminonaphthalene-3,6-disulfonic acid

c) general formulation: D $-^1 \rightarrow$ K $\leftarrow^2-$ D, in words: *p*-nitroaniline $-^1 \rightarrow$ H acid $\leftarrow^2-$ aniline and in reaction equations:

Designation (b) is less commonly used because of its complexity. The practical nomenclature (c) makes use of a genetic scheme of the technically most common synthesis, i.e., it characterizes the azo dye by the starting compounds (D = diazo component and K = coupling component) and the direction of coupling. This nomenclature is shorter and is commonly used in industry and technical literature. In the case of disazo and polyazo dyes, the coupling direction is specified by arrows, the sequence of operations by appropriate numbers above the arrows, and the coupling conditions by the abbreviations a (acid) and alk (alkaline). Additional arrows at the coupling components show the linkage points of both components across the azo groups. All industrially important dyes are also classified according to the Colour Index [7]. This catalog of dyes gives information about trade names, coloristic properties, and, if published, the chemical constitution. The dyes are classified according to color and chemical properties. Aside from its trade names, the azo dye in formula **1**, for example, can be found as C. I. Acid Black 1 or C. I. 20470.

Dyes listed as examples in the following sections are cited according to the internationally used designations in the Colour Index. Trade names are compiled in tabular form only for the individual dye classes; historical common names are for the most part included in the text.

Classification. Azo dyes can be classified either according to chemical guidelines (characteristic chemical groups) or by color aspects (application in dye works). A rigid assignment to one of the two classification systems is possible, but not advisable because of overlapping. There is therefore scarcely a chemical class of azo dyes that belongs to a single color class or vice versa. Moreover, many materials can be dyed with dyes from various color groups. In this article, a compromise between the two classification systems with emphasis on application in the dye works seemed to be the most appropriate.

The importance of the azo dyes is due to their mode of application and to the fact that they represent a clearly defined concept. They are briefly described here and dealt with more extensively under special headings: → Disperse Dyes; → Metal-Complex Dyes; → Pigments, Organic; → Reactive Dyes.

2. Production

For additional information see [1–6] and [8–12].

The processes that are important in the production of azo dyes are classified as follows:

Processes involving synthesis of the azo group:

- diazotization and coupling
- condensation of nitro compounds with amines
- reduction of nitro compounds
- oxidation of amino compounds

Syntheses with compounds already containing the azo group:

- exposure of concealed or protected amino groups
- acylation of aminoazo compounds
- alkylation and acylation of phenolic hydroxyl groups
- metal-complex formation

2.1. Diazotization and Coupling

Of all the industrially important processes azo coupling, during which the azo group is synthesized, is by far the most important. All other industrially employed processes are advantageous only where azo coupling cannot be utilized, for example, because of the unavailability of the starting compounds.

Azo coupling can be summarized as follows: an aromatic amine is linked to a nucleophilic partner RH (coupling component) in the presence of a nitrosyl-eliminating compound XNO to form an aromatic azo compound. The reaction equation is as follows:

$$\mathrm{Ar{-}NH_2 + XNO + RH \xrightarrow{-\,H_2O} Ar{-}N{=}N{-}R + HX} \qquad (1)$$

$$\mathrm{X = Cl,\ Br,\ NO_2,\ HSO_4}$$

Equation (1) describes the overall azo coupling reaction, which consists of two major steps: formation of the diazonium compound by means of the so-called diazotization and synthesis of the azo dye, the actual azo coupling.

2.1.1. Diazotization

Diazotization is defined as the reaction of primary aromatic amines with nitrites, preferably with sodium nitrite, in a usually aqueous mineral acid solution at around 0 °C, whereby the amine is converted into the corresponding diazonium salt:

$$\mathrm{Ar{-}NH_2 + 2\ HY + NaNO_2 \longrightarrow Ar{-}N{\equiv}\overset{+}{N}\ Y^- + NaY + 2\ H_2O} \qquad (2)$$

$$\mathrm{Y = Cl,\ HSO_4,\ etc.}$$

Weakly basic amines require a higher acid concentration, since diazoamino compounds Ar−N=N−HN−Ar may otherwise form. Very weakly basic amines, i.e., amines with several negative (−I/−M) substituents (e.g., tetrahalogen anilines, di- and trinitroanilines, halogennitroanilines) can only be diazotized after being dissolved in concentrated sulfuric acid and subsequently reacted with nitrosylsulfuric acid, HSO_4NO.

A further reason for using concentrated acids (concentrated sulfuric acid) is the fact that diazonium salts of weakly basic amines are readily hydrolyzable in dilute acids.

Diazotization of aromatic diamines gives bisdiazonium compounds and therefore is called bisdiazotization. The incorrect term "tetrazotization" is frequently found in the technical literature.

The essential step in diazotization is the electrophilic nitrosation of the amino group of the primary aromatic amine (**2**).

Formation of the diazonium ion (**4**) then follows via the diazohydroxide (**3**):

$$\underset{\mathbf{2}}{\mathrm{Ar{-}NH_2}} + \mathrm{X{-}N{=}O} \xrightarrow{-\,HX} \mathrm{Ar{-}\overset{H}{\overset{|}{N}}{-}N{=}O} \longrightarrow \underset{\mathbf{3}}{\mathrm{Ar{-}N{=}N{-}OH}}$$

$$\underset{OH^-}{\overset{H^+}{\rightleftharpoons}} \underset{\mathbf{4}}{\mathrm{Ar{-}N{\equiv}\overset{+}{N}}} + \mathrm{H_2O} \qquad (3)$$

$$\mathrm{X = Cl,\ Br,\ NO_2,\ HSO_4}$$

Reaction sequence (3) is a simplification; in fact, the reaction rate during diazotization is determined by the formation of the nitrosating agent (at low acidity) or nitrosation of the amine (at high acidity). In a strongly acid medium, i.e., in the absence of free amines, the protonated amine surprisingly becomes the nucleophile:

$$\mathrm{ArNH_3^+} \overset{NO^+}{\rightleftharpoons} \mathrm{Ar{-}\overset{+}{N}H_2{-}NO} + \mathrm{H^+}$$

$$\mathrm{B} \Downarrow \Uparrow \qquad (4)$$

$$\mathrm{ArNH{-}NO + HB^+ + H^+}$$

The equilibrium reactions preceding nitrosation require excess acid during diazotization leading to the formation of the nitrosating agent:

$$\mathrm{2\ HONO \rightleftharpoons N_2O_3 + H_2O} \qquad (5)$$

$$\mathrm{HONO + H_3O^+ \rightleftharpoons H_2\overset{+}{O}NO + H_2O} \qquad (6)$$

$$\mathrm{HONO + H^+ \rightleftharpoons NO^+ + H_2O} \qquad (7)$$

N_2O_3 is the nitrosating agent in a weakly acid medium (Eq. 5), H_2ONO in a more acid medium (Eq. 6), and the nitrosonium ion NO^+ in a strongly acid medium (Eq. 7).

An excess of sodium nitrite must be avoided, since nitrite can react with the coupling agent as well as with secondary or tertiary amines to form nitroso compounds during subsequent coupling. Excess nitrite can be detected with potassium

iodide–starch paper. It is eliminated by adding amidosulfuric acid or urea:

$$H_2NSO_3H + HNO_2 \longrightarrow H_2SO_4 + N_2 + H_2O$$

$$H_2NCONH_2 + HNO_2 \longrightarrow NH_3 + CO_2 + N_2 + H_2O$$

Diazo Components. Diazo components for the production of azo dyes can be divided into the following groups of aromatic amines:

Aniline and Substituted Anilines. Methyl, chlorine, nitro, methoxy, ethoxy, phenoxy, hydroxyl, carboxy, carbalkoxy, carbonamide, and sulfonic acid groups are primarily used as substituents.

Examples: Toluidines, nitroanilines, aminobenzoyl amides, and the sulfonic acids of these compounds.

Naphthylamines and Naphthylamine Sulfonic Acids. The following compounds, known by their common names, are examples of naphthylamine sulfonic acids:

Many of these compounds can also be used as coupling components (see Section 2.1.2), as shown by the arrow indicating the coupling position.

Diamines $H_2N{-}A{-}NH_2$. The diamines can be divided into four groups:

a) A = phenylene or naphthylene radical, also substituted, e.g., by methyl, chlorine, nitro, methoxy, or sulfonic acid groups. Examples are:

b) A = diphenyl radical, also substituted, mainly by methyl, chlorine, methoxy, carboxylic acid, or sulfonic acid groups. Examples are:

c) A = 
whereby the aromatic rings can also be substituted by methyl, chlorine, methoxy, carboxylic acid, or sulfonic acid groups. B = oxygen, sulfur, $-NH-$, $-SO_2-$, $-N{=}N-$, $-CH{=}CH-$, $-NHCO-$, $-NH-CO-HN-$. Examples are:

d) Heterocyclic amines and diamines. Examples are:

Diazotizing Methods. Considering the basicity and solubility of the amines being diazotized, the following diazotization methods find industrial use (for further details → Diazo Compounds):

a) *Direct Diazotization.* The primary aromatic amine is dissolved or suspended in aqueous hydrochloric or sulfuric acid to which an aqueous, concentrated sodium nitrite solution is added. An excess of 2.5 to 3 equivalents of acid per equivalent of amine is used. A temperature of 0 to 5 °C is maintained by adding ice.
b) *Indirect Diazotization.* Amines with sulfonic or carboxylic acid groups are often difficult to dissolve in diluted acid. Diazotization therefore takes place as follows: the amine is dissolved in water or weak alkalis, and the calculated amount of sodium nitrite solution is stirred into the ice-cooled acid solution already in the vessel. The acid can also be added to the amine–nitrite mixture already at hand.
c) *Diazotization of Weakly Basic Amines.* Weakly basic amines are dissolved in concentrated sulfuric acid and diazotized with nitrosylsulfuric acid, which is easily prepared from solid sodium nitrite and concentrated sulfuric acid.
d) *Diazotization in Organic Solvents.* The water-insoluble or only slightly soluble amine is dissolved in glacial acetic acid or other organic solvents and, where necessary, diluted with water. After the addition of acid it is diazotized in the usual manner with sodium nitrite solution. Nitrosylsulfuric acid, nitrosyl chloride, alkyl nitrites, or nitrous gases can also be used to eliminate the nitrite. Temperature, pH, and the concentration of the diazotizing solution often have a considerable effect on the progress of diazotization. Physical properties (distribution, particle size) and the addition of emulsifiers and dispersing agents influence the diazotization of slightly soluble amines.

Certain aromatic amines require special diazotizing processes:

1-Aminonaphthols, such as 1-amino-2-naphthol and several *1-aminonaphtholsulfonic acids*, such as 1-amino-2-naphthol-4-sulfonic acid, are oxidized to the respective quinone by nitrous acid. Diazotization can however take place under normal conditions in the presence of catalytic quantities of metal salts, such as copper or zinc salts.

o-Diamines, such as 1,2-phenylenediamine or 1,8-naphthylenediamine, undergo cyclization during the normal diazotization process to form triazoles:

The desired bisdiazotization with *o*-phenylenediamine, as well as with *m*- and *p*-phenylenediamine, is achieved in glacial acetic acid with nitrosylsulfuric acid. 1,8-Naphthylenediamine can be bisdiazotized in excess acid.

Under normal diazotization conditions, various *ortho*-substituted aromatic amines also undergo more or less complete cyclization to form benzoheterocycles that are no longer accessible to subsequent coupling.

Examples are:

Diazonium compounds are generally stable only in aqueous solution at low temperatures. When heated, they frequently decompose by eliminating nitrogen to form the corresponding phenol. Some amines, however, can be diazotized at temperatures up to 40 °C. Light and heavy-metal ions also accelerate the decomposition of diazonium compounds. Diazotization, therefore, is usually carried out in wooden vats or iron stirring vessels with an acid-proof lining or rubber coating (see Section 2.5).

As solids most diazonium compounds are stable only to a degree and frequently sensitive to heat, impact, and shock (explosive) (→ Diazo Compounds).

2.1.2. Coupling

Coupling Sequence. The actual azo coupling reaction consists of an electrophilic substitution reaction of the diazonium compound with a nucleophilic partner (coupling component RH):

$$\mathrm{Ar-N^{+}\equiv NY^{-}+R-H \longrightarrow Ar{-}N=N-R+HY} \qquad (8)$$

Coupling components are aromatic systems with nucleophilic centers at the aromatic nucleus, particularly phenols, naphthols, and amines or enolizable compounds with reactive methylene groups. Phenols react as phenolates, naphthols as napththolates, and amines as free bases. According to Equation (8), free acid is formed during the coupling reaction. In order to maintain an optimal reaction sequence, the pH must be kept constant by adding alkalis or buffers. Coupling under strongly alkaline conditions is not possible. According to Equation (3), the diazonium compound undergoes a reverse reaction to form an *anti*-diazotate, which cannot be coupled. Under strongly alkaline conditions and with amines as coupling agents, the diazonium component may react with the amine nitrogen to form the diazoamino compound R−N=N−HN−Ar. Phenols and enols are therefore generally coupled in the weakly alkaline range (pH 7 – 9), amines mainly in the weakly acid range (pH 4 – 7).

In the production of developing dyes for textile printing the formation of diazoamino compounds is desired (see Section 6.1.2, → Diazo Compounds).

Substituents with donor effects in the aromatic nucleus of the coupling components increase the reactivity. Conversely, donor substituents on the lower the reactivity, whereas substituents with acceptor effects increase it. The coupling energy of substituted anilines as diazo components decreases as follows:

polynitroanilines > nitrochloroanilines > nitroanilines > chloroanilines > anilinesulfonic acids > aniline > anisidines > aminophenols.

The C-atom with the highest electron density is usually the preferred coupling position of a coupling component. Due to the directing influence of hydroxyl or amino groups in aromatic systems, coupling takes place at the *ortho* or *para* position. If these two positions are occupied, there is either no coupling or one of the substituents is exchanged. Coupling never occurs at the meta position in relation to the directing substituent. Components of the naphthalene groups generally couple more easily than benzene derivatives.

Amines, which tend to form diazoamino compounds, can easily be coupled at the *para* position if they have been reacted with formaldehyde and sodium hydrogen sulfite to form *N*-methylenesulfonate [13]:

p-Aminoazo dyes are obtained by splitting methylenesulfonate from the coupling products under acid or alkaline conditions.

Other reaction conditions besides pH also play an important role in azo coupling. Increased temperature generally has a greater effect on the decomposition of the diazonium salt according to Equation (9)

$$R-N^{+}\equiv N\,Cl^{-}+H_2O \longrightarrow ROH+N_2+HCl \qquad (9)$$

than on the rate of coupling. The advantages are therefore limited. Coupling can be accelerated by raising the pH and the concentration of the reactants. In some cases the yield of azo dye can be increased by adding sodium chloride prior to the azo coupling. Some azo dyes can only be satisfactorily manufactured by adding pyridine or pyridine homologues; examples are the coupling of diazotized aminoazo compounds and aminodisazo compounds, as well as *o*-aminophenols for the production of complex forming dyes (→ Metal-Complex Dyes).

Pyridine acts as proton acceptor in the electrophilic coupling reaction and is especially beneficial when bulky substituents are present at the *ortho* or *peri* position in relation to the coupling position of the intermediate product or when the diazonium ion (e.g., in the case of *o*-diazophenols) exhibits a slight electrophilic reactivity.

Coupling Components. The most important coupling components can be divided into the following groups. Where there are several possibilities for coupling, the preferred coupling positions are marked by bold arrows and the other possible coupling positions by ordinary arrows.

Anilines, Diaminobenzenes. Examples are:

When reacted with aniline, diazotized aniline (benzenediazonium chloride) yields, apart from a small quantity of 4-aminoazobenzene (**5**), diazoaminobenzene (**6**) as main product:

4-Aminoazobenzene (**5**) is obtained by coupling in a more strongly acid medium, but better still by heating diazoaminobenzene (**6**) in aniline with addition of aniline hydrochloride.

Electron donor substituents in the aniline, such as methyl or methoxy groups, especially at the meta-position, promote the readiness to couple; the inclination to couple thus increases in the sequence aniline $<$ *o*-toluidine $<$ *m*-toluidine $<$ *m*-anisidine $<$ cresidine $<$ 1-amino-2,5-dimethoxybenzene (aminohydroquinone dimethyl ether) to the extent that without formation of the diazoamino compound, the last three bases are attached almost quantitatively in the desired direction, i.e., at the 4-position in relation to the amino group.

m-Phenylene diamines couple to form monoazo dyes (chrysoidines, see Section 5.1.1) or disazo dyes.

Naphthylamines, Naphthylaminesulfonic Acids. Some examples are mentioned here; other compounds can be found among the diazo components (see Section 2.1.1), because most naphthylaminesulfonic acids are capable of being employed both for diazotization and for coupling purposes.

Whereas β-naphthylaminesulfonic acids always couple at the adjacent α-position, with the α-naphthylaminesulfonic acids, the coupling location is influenced by the position of the sulfonic acid group: 1,6-, 1,7-, and 1,8-naphthylaminesulfonic acids couple at the 4-

position; 1,5-naphthylaminesulfonic acid (Laurent acid) only couples with very "strong couplers" (e.g., 2,4-dinitroaniline), mainly at the 4-position. With diazotized aniline, chloroaniline, or diazotized anilinesulfonic acids the 2-aminoazo dyes are obtained, but with diazotized nitroaniline, mixtures of the 2- and 4-coupling products form:

Phenols, Naphthols. Examples are:

Phenols mainly couple at the 4-position, or at the 2-position if the 4-position is occupied. *p*-Hydroxybenzoic acid couples with elimination of CO_2; resorcinol couples twice: initially at the 4-position, with a second equivalent diazonium compound at the 2-position under acid conditions or at the 6-position under alkaline conditions. α-Naphthols mainly couple at the 4-position, in addition to which varying quantities of 2- and 2,4-coupling products are obtained, depending on the diazo component. β-Naphthol couples at the 1-position. Substituents in the 1-position, such as $-SO_3H$, $-COOH$, $-Cl$, $-CH_2OH$, or $-CH_2N(alkyl)_2$, may be eliminated during the coupling process. 1-Methyl-2-naphthol forms no azo dye.

Coupling components in this series that are of particular industrial importance are 2-hydroxynaphthalene-3-carboxylic acid arylamides, in particular anilides, which likewise couple at the 1-position (see Section 6.1.1.2).

Phenols and naphthols generally couple more easily and rapidly than amines; phenol-3-sulfonic acid can be coupled, but not aniline-3-sulfonic acid.

The readiness of the phenols to couple increases as the number of hydroxyl groups rises, as, for example, in the following series:

Naphtholsulfonic Acids. Examples are:

1-Naphtholsulfonic acids mainly couple at the 2-position. The 4-coupling products obtained as byproducts have to be carefully removed from the azo dyes, because unlike the 2-substitution products, their shade changes as a function of the pH value (shade intensification with rising pH due to formation of phenolate or

naphtholate resonance structures; see also Section 3.2.1).

Aminophenols, Aminophenolsulfonic Acids, Aminonaphtholsulfonic Acids. Examples are:

In an alkaline medium *m*-aminophenol couples at the *para* position in relation to the hydroxy group, in an acid solution *p*-hydroxy and *p*-aminoazo dyes are obtained side by side.

In the case of aminonaphtholsulfonic acids, orientation is greatly influenced by the pH value of the coupling medium. For instance, in an acid medium the azo group enters into the position *ortho* to the amino group, in an alkaline medium, in the position *ortho* to the hydroxyl group. 1-Amino-8-naphtholsulfonic acids with free *ortho* positions can couple with two equivalents of diazonium compound, coupling initially taking place in the acid medium at the o-amino position, followed by coupling in the alkaline range at the *o*-hydroxy position. Aminonaphtholsulfonic acids (*o*-hydroxyazo dyes) initially coupled in an alkaline medium cannot normally undergo further coupling to form disazo dyes:

However, if this initial coupling is followed by a metal-complexing process, further coupling is possible in the neutral or alkaline range.

Compounds with Reactive Methylene Groups. In this series the coupling components with the greatest industrial importance are the *N*-acetoacetyl derivatives of aromatic amines (acetoacetic arylides):

$CH_3CO–CH_2CO–NH–Ar$

Anilines substituted by halogen, alkyl, alkoxy, nitro, and acylamino groups are the aromatic amines mainly suitable.

Example:

Bis(acetoacetylamino) derivatives, such as Naphtol AS–G, also enjoy practical importance.

The following coupling components are also listed:

Heterocyclic Components. The most important compounds in this range are the 5-pyrazolones substituted at the 3-position.

Further examples are:

Azo Coupling in Practice. The optimum coupling conditions depend first of all on the nature of the diazo and coupling components used. The acid diazonium salt solution is generally allowed to enter the solution of the coupling component. Because, in addition to acid derived from the diazotization process, additional acid is released during coupling, the optimum pH value must be adhered to by adding bases. Alkali hydroxides, sodium carbonate, sodium hydrogen carbonate, ammonia, calcium carbonate, magnesium oxide etc., are used for this purpose. Such substances as sodium acetate or formiate (weakly acid) or sodium phosphate (weakly alkaline) can also be added to buffer the acid. These substances are added to the reaction mixture before, during, or after combining the components. Because at the feed point of the diazonium salt solution the pH value is always different than after thorough mixing has been completed, the type of stirrer and speed of stirring are also important in many instances. The sequence in which the two components are combined can also greatly influence the result.

The coupling reaction may be completed immediately after the components are mixed or after several hours. If the reaction requires a longer time, it is advisable to cool with ice and avoid exposure to dazzling light. In order to check whether excess diazonium compound is still present, a drop of reaction solution is spotted onto filter paper together with a component that couples easily (e.g., weakly alkaline H acid solution). If no coloration appears, the coupling is completed. The presence of unconsumed coupling component can be determined by spotting with a diazonium salt solution.

Attention must also be paid to the volume of coupling solution or suspension. With starting components of low solubility, the physical state is an important factor. In order to achieve complete reaction of diazo or coupling components with low solubility, it is often necessary to ensure that the reactants are distributed as finely as possible. This is carried out, for example, by adding dispersing agents to the diazo component or to the coupling mixture or by adding emulsifiers during acid precipitation of the coupling component prior to azo coupling. In each case, the most favorable reaction conditions must be precisely established and, because of the various influences that result in undesirable side effects, they must be carefully adhered to during manufacture.

See Section 2.5 for suitable apparatus.

2.2. Other Azo Group Syntheses (See also Chap. 2.4)

2.2.1. Condensation of Nitro Compounds with Amines [2, p. 339]

Aromatic azo and polyazo compounds can be produced by condensation of nitro compounds with amines in accordance with the following equation:

$$R^1\text{–}NO_2 + H_2N\text{–}R^2 \longrightarrow R^1\text{–}N=N\text{–}R^2 + H_2O\,(+O)$$

Because part of the amine is oxidized to the symmetrical azo compound $R^2-N=N-R^2$, an excess of amine is expedient. In some condensation processes it has been possible to observe the partial formation of azoxy bridges. Reaction takes place on heating the reactants for several hours to 40 – 120 °C in aqueous sodium hydroxide solution.

Substituents in the aniline component with electron-donor effects accelerate condensation; electron acceptors retard it. In the nitro component, the substituents have the opposite effect.

Of interest as regards the industrial manufacture of dye intermediates are condensation reactions of 4,4′-dinitrostilbene-2,2′-disulfonic acid

with aromatic amines. If specific sodium hydroxide solution concentrations, temperatures, and reaction times are precisely observed, it is possible with 1,4-diamines, 4-aminophenols, and their sulfonic and carboxylic acids to produce homogeneous monoazo and disazo dyes:

Of importance as regards the industrial production of the important direct cotton dyes for orange, scarlet, and brown shades are condensation reactions of 4,4′-dinitrostilbene-2,2′-disulfonic acid with aminoazo compounds (see Section 4.1.5). For example, by heating this acid with an equivalent of 4-aminoazobenzene-4′-sulfonic acid in aqueous sodium hydroxide solution, the disazo dye **8** is obtained:

Condensation with two equivalents of 4-aminoazobenzene-4′-sulfonic acid at 105 °C in 5 % sodium hydroxide solution results in the corresponding tetrakisazo dye.

The dye synthesis is often followed by an oxidative aftertreatment (with chlorine bleaching liquor) or a reductive aftertreatment in alkaline medium (with sodium sulfide or glucose).

Instead of 4,4′-dinitrostilbene-2,2′disulfonic acid as starting product, use is frequently made of 4-nitrotoluene-2-sulfonic acid, which on being heated with sodium hydroxide solution is converted into dinitrodibenzyldisulfonic acid and dinitrostilbenesulfonic acid. All three nitro compounds condense in the presence of alkali, both with amino compounds and with each other. A number of direct cotton dyes (e.g., *C. I. Direct Yellow 21,* 40045 [*1325-46-8*]) are the result of complex condensation reactions of this type.

Simple azo compounds free of sulfonic acid groups can be produced with yields of 40 – 84 % by condensation of nitrobenzene with *o*- and *p*-anisidine, naphthylamines, and phenylenediamines without solvent in the presence of powdered sodium hydroxide at temperatures of 130 – 190 °C [14].

Because these reactions can proceed very vigorously, suitable precautionary measures are necessary.

2.2.2. Reduction of Nitro Compounds [2, p. 346]

During the reduction of aromatic nitro compounds, condensation of the nitro and hydroxylamino derivatives that occur as intermediate steps may result in the formation of azoxy compounds, which in a further reduction step can be converted into azo compounds:

The method is only suitable for the synthesis of symmetrical azo compounds, for when two different nitro compounds are used, mixtures of all possible combinations are formed:

Glucose has proved especially suitable as a reducing agent for reductive linkage of aromatic nitro compounds, other reducing agents being alcohols, hydrazine, zinc, iron, and numerous inorganic salts. Only the reduction process with glucose has attained industrial significance in the synthesis of azo dyes, mainly for the linkage of nitroazo compounds under mild conditions. The

process generally takes place in a strongly alkaline, aqueous medium, less frequently in an alcoholic medium. For example, the red trisazo dye *C. I. Direct Red,* 25015 [*6391-13-5*] is obtained by coupling 2-methyl-5-nitroaniline to Nevile-Winther acid and subsequently treating with glucose and alkali:

Reduction by glucose often does not proceed quantitatively up to the azo stage; instead the azo and azoxy compounds are mostly formed side by side. Where necessary, therefore, subsequent reduction of the azoxy compound to form the azo dye must follow.

2.2.3. Oxidation of Amino Compounds [2, p. 371]

Reaction of primary aromatic amines with suitable oxidizing agents results in symmetrical azo compounds, sometimes, by further oxidation of the azo stage, in the mixture with azoxy compounds:

Hypochlorites are especially suitable as oxidizing agents, others being peroxy compounds (hydrogen peroxide, sodium perborate), oxygen or air in the presence of a pyridine – Cu(I)chloride catalyst, and chromic acid.

The main industrial application for the oxidative linkage of aromatic amines in the synthesis of azo dyes can be found in the thiazole range. The yellow cotton dye *C. I. Direct Yellow 28*, 19555 [*10114-47-3*], for example, is obtained by treating an aqueous solution of the sodium salt of the so-called dehydrothiotoluidinesulfonic acid (**9**) with sodium hypochlorite in an alkaline medium:

2.3. Synthesis from Azo Compounds

For specific technical purposes in the production of azo dyes, further reactions are carried out on the azo compound after introduction of the azo bridge:

- exposure of concealed or protected amino groups
- acylation of aminoazo compounds
- alkylation and acylation of phenolic hydroxyl groups
- metal-complex formation

2.3.1. Exposure of Concealed or Protected Amino Groups

The formation of an amino group in azo dyes is often necessary for the reaction with acid chlorides, e.g., for the production of reactive dyes, or for further diazotization and coupling. This is possible by reduction of nitro groups or by saponification of acylamino groups.

As the reduction of nitro groups must be carried out while maintaining the azo group, the number of suitable reducing agents is virtually restricted to sodium sulfide. Processing is carried out, depending on the nitro compound, in an aqueous alkaline solution or suspension at temperatures between 20 °C and 90 °C. A 10 – 30 % addition of alkali chloride has proved favorable, as a result of which most of the dye remains undissolved. After reduction the water-soluble sulfide oxidation products are separated, the dye is dissolved, and the sulfur is separated. The amino azo dye can be further processed straightaway in this form.

The acylamino groups, such as formyl, acetyl, or oxalylamino groups can be saponified in an acid or alkaline medium. As a rule 2 – 10 %

sulfuric acid or 2 – 6 % sodium hydroxide solution is used at temperatures up to the boiling point of the reaction mixtures.

2.3.2. Acylation of Amino Azo Compounds
[2, p. 390]; [5, vol. VI, p. 1]

Acylation reactions of aromatic amino compounds are important both for the production of reactive dyes, i.e., dyes that in the dyeing of textiles form a covalent bond with the fiber (→ Reactive Dyes), and for the synthesis of direct dyes (see Section 4), i.e., dyes that, because of their pronounced affinity for cellulosic fibers (substantivity), are adsorbed directly onto the cotton fiber from an aqueous solution.

Acylation agents that contain at least two reactive centers in the molecule and are capable of selective reactions under certain conditions, e.g., cyanuric chloride and cyanuric fluoride (**10**), 2,3-dichloroquinoxaline-6-carboxylic acid chloride (**11**) and chlorotrifluoropyrimidine (**12**), are used for the synthesis of a relatively large number of reactive dyes.

10 11 12

X = Cl or F

The reactive dyes most widely used so far are the chlorotriazinyl dyes, which can be produced on an industrial scale from dyes Ⓕ–NH_2 containing amino groups and cyanuric chloride, with cleavage of hydrogen chloride, in an aqueous organic medium at 0 – 5 °C and at a pH-value of 6.5 – 7.0. They can be condensed with an aliphatic or aromatic amine or even with a second dye Ⓕ–NH_2 at 40 to 50 °C to form the less reactive monochlorotriazinyl dyes:

For the production of substantive dyes two identical or different aminoazo dyes are linked together by means of cyanuric chloride. The third chlorine atom remains either in the molecule or, preferably, is condensed with ammonia or simple aromatic amines at temperatures of 80 – 100 °C. The reaction with cyanuric chloride not only enables the inner-molecular blend to be varied at will but also considerably increases substantivity.

Phosgene, which is introduced into the solution of the amino azo compound at 20 – 35 °C and at a neutral pH, is used as a bifunctional acylation agent to link two amino azo compounds (see Section 4.1.6).

Numerous commercial dyes of a substantive nature have urea bridges of this kind, e.g., the direct dye *C. I. Direct Yellow 50,* 29025 [*8004-79-3*], which is produced from diazotized 2-aminonaphthalene-4,8-disulfonic acid and *m*-toluidine by reaction of the azo dye with phosgene:

2.3.3. Alkylation and Acylation of Phenolic Hydroxyl Groups [2, p. 403]

Alkylation. To overcome the poor alkali fastness of *p*-hydroxyazo dyes (see Section 3.2.1) the phenolic OH groups can be converted into alkyl ether with such alkylation agents as dialkyl sulfate, alkyl halides, epoxides, etc. Depending on the water solubility of the *p*-hydroxyazo dyes, processing is carried out in weakly alkaline aqueous solution or in organic solvents, such as dimethylformamide or ethylene glycol dimethyl ether, under alkylation conditions, such as are usual with aromatic hydroxy compounds. The synthesis of *p*-alkoxyazo compounds by heating hydroxyazo compounds in an alcoholic medium with the addition of acid is of interest, e.g.:

The reaction represents the inversion of the acid-catalyzed hydrolysis of azoaryl ethers.

On a large industrial scale hydroxyazo compounds are mainly reacted with ethyl chloride in aqueous alkaline solution (sodium carbonate, sodium hydroxide) by heating for several hours to temperatures of around 100 °C in a closed system.

Acylation. Here aryl sulfonation plays a particularly important role. In order to convert them into arylsulfonic acid esters, hydroxyazo dyes are reacted with arylsulfonic acid chlorides, mainly *p*-toluenesulfonic acid chloride or benzenesulfonic acid chloride in an aqueous alkaline medium. The formation of arylsulfonic acid esters not only overcomes the poor alkali fastness of *p*-hydroxyazo dyes but, with wool dyes, also improves the fastness to washing and milling and the neutral affinity.

2.3.4. Metal-Complex Formation

For more details → Metal-Complex Dyes and [15], [2, p. 434].

Azo dyes with certain structural groupings are capable of forming metal-complex compounds. Here even the coupling component, such as salicylic acid, can form a complex:

Technically far more important than these metal complexes, most of which are produced on the fiber (see chrome dyes, Section 3.2.1.3), are those dyes whose metal complexes are produced within the dye itself. Here the complex is always formed with the participation of the azo group. These dyes have complex-forming substituents in the *o,o′* position relative to the azo bridge and are, for instance, capable of forming 1 : 1 metal complexes of the general formula **13**.

13

The azo dye anion always acts as a divalent ligand in threefold coordination. The remaining coordination positions of the metal ions are filled by addition of further ligands with lone electron pairs (e.g., H_2O, NH_3, amines) or by another azo dye anion (formation of 1 : 2 metal complexes).

Suitable complex-forming metals are in particular the trivalent chrome and trivalent cobalt (coordination number 6) and also the divalent copper and nickel (coordination number 4), whose complex dyes have great industrial importance.

One of the hydroxyl groups in the *ortho* position relative to the azo bridge can only be formed during metallizing by cleavage of an *o*-methoxy group. This demethylating metallizing process has been introduced on an industrial scale because of the wide variety of diazo components to choose from [15].

The addition of copper to the molecule in an oxidative process, in which a hydrogen atom in the *ortho* position relative to the azo group is converted into the appropriate hydroxyl group by means of oxidizing agents, such as hydrogen peroxide, has acquired technical significance [16]:

Chrome-complex dyes are best used as dyes for wool, polyamide, and leather and for coloring paints and plastics; copper complexes are used as cotton and leather dyes and also as pigments; and chrome and cobalt complexes, as spirit-soluble dyes.

2.4. Processes without Industrial Importance

Of the processes for producing azo dyes via synthesis of the azo group, the following are worth mentioning, although they have attained no industrial importance so far:

- reduction of diazonium compounds
- oxidative coupling
- dehydrogenation of diarylhydrazines
- reaction of arylhydrazines with quinones

– condensation of nitroso compounds with amines
– azo compounds from azido compounds

2.4.1. Reduction of Diazonium Compounds
[2, p. 320, 323]

When aromatic diazonium compounds are reacted with ammoniacal copper(I) salt solution, diarylazo compounds or diaryls are obtained with elimination of nitrogen

The course of the reaction depends on the type of substitution on the aromatic nucleus: whereas electron-attracting substituents result in diaryl formation, diazonium salts in which the substituents on the nucleus are electron donors can be converted to symmetrical azo compounds (Vorländer reaction) [17], [18]:

The action of sulfurous acid or its salts on diazonium compounds of the naphthalene series results in the formation of symmetrical azo compounds; the starting compounds may also contain electron-attracting substituents (Lange reaction) [19], e.g.:

Studies by SUCKFÜLL and DITTMER have shown that in this process the diazonium salt reacts with the diazosulfonate formed from sulfite and diazonium ion [20]:

Whereas in the Lange reaction (see Eq. 10) the two aryl radicals are identical, SUCKFÜLL and DITTMER were able to expand the reaction of diazonium salt and diazosulfonate for the synthesis of asymmetrical azo compounds and, with certain restrictions, extend it to the azo series. The significance of the reaction lies in the access to azo compounds that are very difficult to synthesize by conventional means, e.g.:

2.4.2. Oxidative Coupling

Of interest from the preparative and theoretical aspects is the oxidative azo coupling process discovered by S. HÜNIG, through which many heterocyclic azo compounds have become accessible [21].

A precondition of the reaction is the presence of a heterocyclic hydrazone, which couples with aromatic amines, phenols, or compounds with active methylene groups in the presence of dehydrogenating agents to form the corresponding azo compounds, e.g.:

As regards the coupling components and the coupling location, the reaction resembles the azo coupling process. As electrophilic component, a diazonium ion **14** is suggested, which is formed from the hydrazone component through the action of the dehydrogenating agent and reacts by electrophilic substitution with the coupling component with the loss of two hydrogen atoms to form the azo compound.

14

In the case of phenols and α-naphthols, the attack in principle always takes place at the *p*-position. Only when the *p*-position is occupied does coupling occur at the *o*-position. The optimum phenylazo compound yield (approx. 90 %) is attained at pH 9. The dehydrogenating agents mainly used for this purpose are potassium hexacyanoferrate(III), copper(II) sulfate, silver nitrate, sodium hypochlorite, or lead(IV) oxide.

The optimum pH range for oxidative coupling with aromatic amines and enamines is pH 1 – 3, diluted hydrochloric acid or glacial acetic acid being preferred as reagents. Well-tried dehydrogenating agents for this purpose are iron(III) chloride, red lead, lead(IV) oxide, and lead(IV) acetate.

In order to obtain an optimum yield, reagent and oxidizing agent should in each case be carefully matched to the coupling component used. Oxidative coupling has so far rarely been used for industrial production of azo dyes.

2.4.3. Dehydrogenation of Diarylhydrazines [2, p. 377]

N,N′-Diarylhydrazines can be dehydrogenated to form azo compounds:

$$\mathrm{Ar-NH-NH-Ar'} \xrightarrow{-2\mathrm{H}} \mathrm{Ar-N=N-Ar'}$$

Oxidizing agents frequently used are sodium hypochlorite or air in the alkaline, or iron(III) chloride or sodium dichromate in the acid medium, as well as nitrous acid. The method acquires importance when the azo compounds to be synthesized are not accessible by coupling or condensation reactions, or only with difficulty, and the relevant diarylhydrazines can be obtained by simple reactions, e.g.:

2.4.4. Reaction of Arylhydrazines with Quinones [2, p. 355]

Benzo- and naphthoquinones as well as quinones of some polycondensed aromatics react in an acid aqueous or aqueous alcoholic medium or in acetic acid to form hydroxyazo compounds, tautomers of quinone hydrazones, e.g.:

The reaction proceeds along the lines of this condensation process only if the oxidizing power of the quinone and the reduction potential of the hydrazine are not at such a high level that formation of hydroquinone takes place via a redox reaction. Quinones with a high oxidation potential (e.g., *p*-benzoquinone) can thus only be reacted with arylhydrazines (e.g., *o*- and *p*-nitrophenylhydrazine) and vice versa.

Of significance is the reaction of the quinones with arylhydrazines to form azo compounds, when the latter are difficult to obtain by azo coupling, e.g., 1-hydroxy-2-phenylazonaphthalene:

Instead of quinones, it is possible to react their monoximes with arylhydrazines, e.g.:

The hydroxylaminoazo compounds formed (**15**) react with nitrous acid to form azo diazo-

nium compounds (**16**), preliminary stages for the synthesis of polyazo dyes.

Arylhydrazines can also be converted into azo compounds by condensation with other dioxo compounds, provided this possibility is permitted by the keto-enolic tautomerism. An interesting example of this is the reaction of dioxosuccinic acid with two equivalents of phenylhydrazine-4-sulfonic acid, which with simultaneous formation of the pyrazolone ring results in tartrazine (*C. I. Acid Yellow 23,* 19140 [*1934-21-0*]), the oldest dye in this class:

(11)

2.4.5. Condensation of Nitroso Compounds with Amines [2, p. 332]

Azo and polyazo compounds can be produced by condensation of amines with nitroso compounds, very good yields being frequently obtained:

Depending on the substitution of the aromatic rings, the reactions are carried out at room temperature or at temperatures of up to about 100 °C. The reagent used is almost always acetic acid on its own or in mixtures with other organic solvents. Other reagents, such as water or alcohols, cause a sharp decrease in yield. The influence of substituents on the reaction rate is analogous to that in nitro – amine condensation (see Section 2.2.1).

Whereas nitroso – amine condensation is not generally possible in the naphthalene range, its use in the benzene range mainly serves the production of asymmetrically substituted azo compounds and the formation of polyazo compounds. It has no industrial importance in the production of azo dyes.

2.4.6. Azo Compounds from Azido Compounds

Compounds containing active methylene groups react with organic azido compounds in the presence of a base, with formal substitution of a diazo group for two hydrogen atoms (diazo group transfer) [22]:

The resulting diazo compound (**19**) can be coupled with a second molecule of the methylene compound (**18**) to form a symmetrical azo compound (**20**):

p-Toluenesulfonic acid azide (**17**, R = $CH_3C_6H_4SO_2-$), readily obtainable from *p*-toluenesulfonic acid chloride, has, in particular, proved to be a suitable azido compound.

The method permits the synthesis of a number of interesting heterocyclic azo compounds, e.g.:

So far, however, it has been of no industrial importance.

2.5. Equipment for Industrial Production of Azo Dyes

Production of azo dyes on an industrial scale is still carried out on a batchwise basis.

The main items of equipment for industrial diazotization and coupling are the diazotizing vessel, the dissolving tank for dissolving the coupling component, and the central coupling tank with capacities between 25 and 80 m^3. Coupling batches of up to 8 kmol per batch can thus be processed.

Figure 1 illustrates the flow diagram and main items of equipment in a simple industrial azo dye synthesis.

Figure 1. Equipment diagram for the production of an azo dye
a) Diazotizing tank; b) Dissolving tank; c) Clarifying press; d) Coupling vessel; e) Filter press; f) Drying and milling

In the simplest case, the solution of the coupling component is transferred to the coupling vessel after mechanical and adsorptive clarification by means of a clarifying press or a filter, and the diazonium salt solution, likewise after clarification, is added slowly above or below the surface of the coupling component solution. The solutions can also be added in the reverse sequence or both at the same time from the diazotizing and dissolving tank. The constancy of the reaction temperature and of a narrow pH range is a decisive factor as regards the coupling process and must be continuously monitored by means of suitable measuring devices. The coupling reaction can be followed in the coupling tank or other vessels by other reactions, such as saponification, esterification, acylation, or metal-complexing processes, which if necessary must be carried out under pressure and at higher temperatures.

Following the synthesis and any thermal aftertreatment process that may be required, azo dyes insoluble in water (e.g., pigments, disperse dyes) can be directly isolated by means of filter presses or suction filters. For large-volume products, preference is given to continuously operating rotary filters.

Water-soluble azo dyes (e.g., reactive dyes, acid dyes, or direct dyes) must be precipitated from the coupling solution (coupling liquor) by salting out or changing the pH. If in addition to the salt content other impurities in the dye are permissible, the spray drying process is used for separating water-soluble azo dyes from the reaction solution.

Depending on the requirements regarding corrosion resistance and ability to withstand compressive and thermal stress, the *materials* used for industrial equipment are iron, stainless steel, rubber-coated steel with or without an acid-proof lining, enameled steel, glass fiber reinforced synthetic resins, and wood.

In general, diazotizing, dissolving and coupling vessels are nowadays made from rubber-coated steel. The hard rubber lining can be exposed without damage to temperatures of up to 100 °C; contact with organic solvents should be avoided. Use has also been made of coupling tanks made from glass fiber reinforced synthetic resins (low weight, low cost, easy to repair), which are resistant to hydrochloric acid and can be exposed to temperatures of up to 100 °C. Wooden vats are still of importance in the industrial manufacture of azo dyes, primarily because of their corrosion resistance in aqueous systems, combined with low capital expenditure and repair costs. For reactions in an alkaline medium and in organic solvents, as well as for reactions under pressure, stainless steel tanks are employed. Stainless steel tanks and other items of equipment made from this material are not resistant to corrosion by mineral acid solutions. Stainless steel must also be avoided for reactions of weakly acid or salt-containing solutions carried out under pressure. Enameled equipment is used for reactions in acid media performed under pressure, but is not resistant to alkalis. Its advantage lies in its easy cleaning.

For reactions under pressure in an acid medium, rubber-coated and brick-lined steel tanks with agitators, heating coils, and thermometer tubes made from Hastelloy (nickel alloys with varying Mo, Cr, Mn, Cu, Si, Fe, and C contents) have also proved suitable. Brick-lined vessels are chiefly employed in large-capacity equipment, when the use of enameled vessels is dispensed with because of the high capital expenditure and repair costs involved.

In the industrial production of azo dyes in equipment that cannot be placed under pressure (wooden vats, drums made from synthetic resins), pumps are needed in order to convey the tank contents from vessel to vessel or via clarifying presses and filter presses. When steel drums are used, the solutions and suspensions are often transferred by air or nitrogen pressure.

3. Anionic Azo Dyes [1], [3], [4], [7], [5, vol. I, p. 480; vol. III, p. 268]

3.1. Introduction

Anionic dyes include many compounds from the most varied classes of dyes, which exhibit characteristic differences in structure (e.g., azoic, anthraquinone, triphenylmethane, and nitro dyes) but possess as a common feature water-solubilizing, ionic substituents. The anionic azoic dyes, which are discussed here, constitute the most widely used group of this class of dyes.

Most often sulfonic acid groups serve as hydrophilic substituents, because they are readily introduced and, as strong electrolytes, are completely dissociated in the acidity range used in the dyeing process. Almost invariably the products manufactured and employed are water-soluble sodium salts of the sulfonic acids.

Direct Dyes. In principle the anionic dyes also include direct dyes, but the latter, because of their characteristic structures, are used to dye cellulose-containing materials and go onto the fiber from a neutral dye bath. Because the classification used here is based chiefly on the dyes' application in the dyehouse, direct dyes are discussed in a separate chapter (see Chap. 4).

Reactive Dyes. From the chemical standpoint the group of anionic azo dyes includes a large proportion of the reactive dyes which, in addition to the usual structural characteristics, also contain certain reactive groups capable of reaction with functional groups of the fiber during the dyeing process, for example, with the hydroxyl groups of cellulose, the amino and mercapto groups of wool and silk, or the amino and carbonamide groups of synthetic polyamides. Owing to the covalent dye – fiber bond these dyeings usually exhibit good fastness to wet processing.

For structures of reactive dyes for wool and polyamide → Reactive Dyes.

Metal-Complex Dyes. The anionic azo dyes also including the metal-complex dyes, which are derived from *o,o′*-disubstituted azo dyes and which can be metallized not only on the fiber but whose metal-complex compounds are applied largely in the form of a complete dye (cf. Section 2.3.4). They serve for the dyeing of wool (see Section 3.2.1.4), silk and leather (Section 3.2.4) and polyamide (see Section 3.2.2), and also for cotton (see Section 4.1.8) and as alcohol- and ester-soluble dyes (see Section 6.1.2). This dye class, too, is discussed only briefly here; for details → Metal-Complex Dyes.

3.2. Acid Azo Dyes

This group of substances also includes dyes that are classified under other headings, → Anthraquinone Dyes and Intermediates, → Nitro and Nitroso Dyes; → Triarylmethane and Diarylmethane Dyes.

Azo dyes with relatively low molecular masses and one to three sulfonic acid groups serve as so-called acid azo dyes for dyeing and printing wool, polyamide, silk, and basic-modified acrylics and for dyeing leather, fur, paper, and food. The main area of application is the dyeing of wool and polyamide.

Individual dyes also play a part in the manufacture of color lakes, which are used to pigment printing inks and for coloring plastics.

Disazo and polyazo dyes containing sulfonic acid groups are also frequently used in the above applications. Many of them are also sold as substantive dyes for cotton because of their pro-

nounced affinity toward cellulosic fibers (see Chap. 4).

The term "acid dye" derives from the dyeing process, which is carried out in an acidic aqueous solution (pH 2 – 6).

Protein fibers contain amino and carboxyl groups, which in the isoelectric range (approximately pH 5) are ionized mostly to $-NH_3^+$ and $-COO^-$. In the acid dyebath the carboxyl ions are converted to undissociated carboxyl groups owing to the addition of acid HX (sulfuric or formic acid), which causes the positively charged wool ($H_3N^+-W-COOH$) to take up an equivalent amount of acid anions X^- (hydrogen sulfate, formate) [23]:

The actual dyeing process consists of a replacement of the absorbed acid anions X^- by the added dye anions $Ⓕ^-$, since the latter exhibit a much greater affinity for the substrate than the much smaller acid anions. Thus the dye is bonded to the wool not only by electrostatic attraction (salt formation) but also by its more or less strong affinity for the fiber.

Acid dyes are divided into three groups based on their differences in affinity, which is primarily a function of the molecular size.

1) *Leveling dyes* are relatively small molecules which form a saltlike bond with the protein fiber. This not very tight bond imparts good migration properties to such dyes on wool. The interplay between the bonded dye and the dye still in the dyebath results in very uniform, *level* dyeings. On the other hand they possess only poor wetfastness, so that the use of leveling dyes is severely limited.
2) *Milling dyes* are large-volume dye molecules, for which salt formation with the fiber plays only a secondary role and the adsorption forces between the hydrophobic regions of the dye molecule and those of the protein fiber predominate. The resulting tighter bond yields good wetfastness, but the levelness of the dyeings is not always satisfactory because of an inadequate migration property. In consequence the range of applications of milling dyes is also limited.
3) *Dyes with intermediate molecular size* not only form a saltlike bond with the wool fiber but are also bonded to the fiber by intermolecular forces and have properties lying in an intermediate position between those of the leveling and the milling dyes. They are used mainly where average requirements are placed on the wetfastness and levelness of the dyeing.

Concerning the possibility of influencing the rate of dyeing and the leveling power during the dyeing process by the addition of acid or color salt → Dyes, General Survey.

3.2.1. Wool Dyes

The standard dyes for wool are divided essentially into four groups according to their different dyeing behaviors (cf. Table 1).

Table 1. Names of important ranges of acid wool dyes

Manufacturer	Ranges			
	Group A	Group B	Group C	Group D
Bayer	Acilan	Supracen	Supranol	Supramin
Ciba-Geigy	Erio	Eriosin	Polar	
Hoechst	Amido	Lanaperl	Alphanol Fast	
ICI	Lissamin	Coomassie	Carbolan	
Sumitomo		Suminol leveling	Suminol milling	
Sandoz		Sandolan-E	Sandolan-N	

Group A contain the low-priced, usually older leveling dyes with moderate light fastness. These dyes are still used in larger quantities for cheap articles.

Group B also includes leveling dyes, which are applied in a strongly acid bath but which exhibit very good light fastness.

Group C contains the milling dyes, which are applied in a weakly acid to neutral bath.

Group D contains the acid dyes with good leveling properties, intermediate molecular sizes, and for the most part good light fastnesses.

The product ranges of the various dye manufacturers do not completely fulfill the demands made on the dyes in respect of the individual

fastnesses, and within a manufacturer's range the properties of the dyes can be individually specified.

In describing the separate dye types it is useful to distinguish between the monoazo and the disazo dyes, and to further break down the disazo dyes into primary and secondary types on the basis of chemico-structural principles.

In the industrial manufacture of acid azo dyes usually aniline derivatives are used as the diazo components and for disazo dyes also diaminodiphenyl derivatives and other bifunctional diamines. The coupling components for orange to blue shades are commonly aniline, naphthylamine, naphthol, and aminonaphthol derivatives, whereas phenylpyrazolones are much used for preparing dyes in the yellow and orange shades.

In regard to the stability of the shade to changes in pH, care must be taken that hydroxyl or amino groups lie adjacent to the azo group in order to form a hydrogen bridge with the latter. This hydrogen bridge prevents a dissociation of the hydroxyl groups or a protonation of the amino groups and hence avoids an unwanted change in shade in response to moderate pH shifts. Groups that are not in the *ortho* position must be alkylated or acylated (see Section 2.2.3).

3.2.1.1. Monoazo Dyes

Among the acid monoazo dyes are a number of much used wool dyes that possess no outstanding coloristic properties but that are distinguished by brilliance of shade, very good leveling power, and particularly low cost, while their wash fastness and light fastness meet only low to medium requirements. Partly influenced by the introduction of the International Woolmark to label high-quality wool articles, the fastness requirements have risen considerably in the last 20 years, which has necessitated the development and manufacture of particularly fast dyes. For this reason many, and above all the older, acid dyes have lost all importance for the dyeing of wool and are used today only for the coloring of paper, soaps, food, and cosmetics.

In the following discussion the acid monoazo dyes are classified according to the type of coupling component.

Aromatic Amines as Coupling Components. One of the oldest azo dyes is *C. I. Acid Yellow 36,* 13065 (metanil yellow) (**21**) [*587-98-4*].

21

Because of the basic group suitable for salt formation the dye is not fast to acid, but it is still used today for dyeing wool and in special areas (leather and paper) primarily for price reasons.

Coupling H acid to 1-(phenylamino)naphthalene-8-sulfonic acid (*N*-phenylperic acid) yields *C. I. Acid Blue 92,*13390 (**22**) [*3861-73-2*].

22

On wool the product turns out a very pure blue of good light fastness and with moderate wet fastness and adequate leveling power.

Naphthols and Naphtholsulfonic Acids as Coupling Components. In this series two important acid dyes with very similar structures are *C. I. Acid Red 88,* 15620 (**23**) [*1658-56-6*], derived from diazotized naphthionic acid and 2-naphthol, and *C. I. Acid Red13,* 16045 (**24**) [*2302-96-7*], from naphthionic acid and Schäffer's acid:

23 **24**

Both are all-purpose dyes which, because of their attractive red shades, are still in use today in many areas of textile dyeing and also for leather and paper dyes. Wool dyeings produced with these dyes exhibit moderate fastness levels.

A long-known, inexpensive, but only moderately fast dye is *C. I. Acid Orange 7,* 15510 (Orange II) (**25**) [*633-96-5*]. As a wool dye it is now of secondary importance, but is used in special areas such as leather dyeing, paper coloration, and the manufacture of color lakes.

25

26

A previously much used red wool dye is *C. I. Acid Red 14,* 14720 (**26**) [*3567-69-9*], which is now used to a limited extent in wool dyeing for inexpensive articles.

The usually very low wetfastness of these simple acid azo dyes can be improved at the expense of leveling power by the introduction of special, large-volume substituents. Example: *C. I. Acid Orange 19,* 14690 (**27**) [*3058-98-8*], is a very important acid dye for wool and polyamide with good fastness properties and yet with good leveling power.

27

Aminonaphtholsulfonic Acid as the Coupling Component. Important coupling components are γ *acid* (2,8-aminonaphthol-6-sulfonic acid) and *H acid* (1,8-aminonaphthol-3,6-disulfonic acid), from which many important wool dyes are derived, some of which exhibit very good light and wetfastness.

Especially in acid coupling γ acid yields dyes with very good light fastness, which is presumably attributable to the formation of a hydrogen bridge between the azo bridge and the hydroxyl group *peri* to the azo bridge.

As examples are cited two outstandingly lightfast dyes of good leveling power whose dyeings on wool exhibit moderate wetfastness: *C. I. Acid Red 42,* 17070 (**28**) [*6245-60-9*], and *C. I. Acid Red 37,* 17045 (**29**) [*6360-07-2*].

28

29

Through the choice of suitably substituted diazo components, bluish red to blue wool dyes with good light and wetfastnesses can be produced. Example: *C. I. Acid Violet 14,* 17080 (**30**) [*4404-39-1*].

30

Of interest is the manufacture of 4-amino-3-(4′-toluenesulfonyl)acetanilide, which is used as the diazo component: *p*-phenylenediamine is oxidized with iron(III) chloride to 1,4-benzoquinonediimine, to which *p*-toluenesulfinic acid is added. The final step is partial acetylation:

Further examples are: *C. I. Acid Red 32,* 17065 (**31**) [*6360-10-7*], and *C. I. Acid Blue 117,* 17055 (**32**) [*10169-12-7*].

31

32

On wool both dyes exhibit quite good wetfastness and high leveling power.

In order to achieve valuable dyes with alkaline coupling to γ acid, the amino group must be acylated or arylated. Example: *C. I. Acid Red 68,* 17920 (**33**) [*6369-40-0*].

33

On wool it exhibits high leveling power and yields light- and wetfast dyeings.

N-arylation of γ acid results in a strong deepening of the shade. The usually brown to black dyes thus obtained are fast to light and milling and go onto wool and silk from a neutral liquor. Example: *C. I. Acid Brown 20,* 17640 (**34**) [*6369-33-1*].

34

An important coupling component is H acid. Realization that acylation of its amino group substantially improves the light fastness and in addition yields dyes with good leveling power led to many valuable light- and wetfast products that even today occupy a firm position on the market. A relatively simply structured wool dye, *C. I. Acid Red 1,* 18050 (**35**) [*3734-67-6*] is obtained by the alkali coupling of diazotized aniline to *N*-acetyl H acid.

35

Valuable dyes can also be made with *N*-benzoyl H acid and *N*-toluenesulfonyl H acid.

An interesting development is the *Carbolans* of ICI. Their neutral affinity to wool and very good wetfastness properties are achieved by incorporating long hydrophobic hydrocarbon radicals [5, vol. III, p. 268]. Example: *C. I. Acid Red 138,* 18073 (**36**) [*15792-43-5*].

36

1-Phenyl-5-pyrazolones as Coupling Components. Especially lightfast yellow shades are obtained by using 1-phenyl-5-pyrazolones as coupling components. The first representative of the class to appear was Tartrazine, *C. I. Acid Yellow 23,* 19140 [*1934-21-0*], which is formed in a smooth reaction when phenylhydrazine-4-sulfonic acid is heated with dioxosuccinic acid (see Eq. 11, Section 2.4.4). Today the starting compound is 1-(phenyl-4′-sulfonic acid)-3-carboxy-5-pyrazolone, which can be obtained from oxaloacetic ester and phenylhydrazine-4-sulfonic acid and can be coupled with diazotized sulfanilic acid. Tartrazine is an intense yellow, moderately fast dye that is still important in wool dyeing but is also used in the dyeing of leather, the coloring of paper, soap, and food, and in the lake form as a pigment.

For price reasons the 1-aryl-3-methyl-5-pyrazolones and their derivatives are preferred to the corresponding 3-carboxypyrazolones. There is such a wide range of possible variations that dyes in this series extend from greenish yellow to reddish orange. Examples: *C. I. Acid Yellow 17,* 18965 (**37**) [*6359-98-4*].

37

On wool the product yields a clear, superbly lightfast yellow with good to very good general fastness properties, but relatively poor milling fastness.

C. I. Acid Yellow 76, 18850 (**38**) [*6359-88-2*], is obtained by coupling diazotized 4-aminophenol to the pyrazolone component and then esterifying with *p*-toluenesulfonic acid chloride in an alkaline medium. The toluenesulfonic ester group substantially improves the fastness to milling and makes the shade obtained largely independent of pH; the light fastness is not quite as good as that of Acid Yellow 17.

38

3.2.1.2. Disazo Dyes

Dyes with two azo groups are divided on chemico-structural principles into primary and secondary disazo dyes. Primary disazo dyes are manufactured either according to the scheme $D_1 \rightarrow K \leftarrow D_2$ from a bifunctional coupling component K and two identical or different diazo components D_1 and D_2, or according to the scheme $K_1 \leftarrow D \rightarrow K_2$ by coupling a bisdiazotized diamine D to the coupling components K_1 and K_2, which may be the same or different. Secondary disazo dyes are manufactured according to the scheme $D \rightarrow M \rightarrow K$ (M = middle component) from a diazotized aminoazo dye ($D \rightarrow M$) and a coupling component K (series coupling).

Primary disazo dyes of the type $D_1 \rightarrow K \leftarrow D_2$ are obtained by twofold coupling to, for example, resorcinol. These orange to brown dyes have poor light and wetfastness and are used only for inexpensive leather dyeings. Among the naphthalene derivatives H acid is one of the most important; it serves as a bifunctional coupling component K for the manufacture of many wool dyes now in use.

Dye synthesis following the above scheme generally permits little variation of the shade (black, dull brown, and blue), because completely conjugated chromophoric systems are formed.

One of the most important acid dyes is *C. I. Acid Black 1,* 20470 (**39**) [*1064-48-8*].

39

It dyes wool in blue-black shades with very good light fastness but only moderate wetfastness. Nevertheless, because of its high affinity and good leveling power it has remained an important product, which through shading with yellow, orange, or red forms the basis of most black acid dyes. To manufacture this type of dye, coupling is always first carried out in an acid medium with the more strongly electrophilic diazonium salt, here with diazotized 4-nitroaniline, then in the alkaline range with diazotized aniline:

$$\text{4-nitroaniline} \xrightarrow[\text{a}]{1} \text{H acid} \xleftarrow[\text{alk.}]{2} \text{aniline}$$

Abbreviated manufacturing instructions for C. I. Acid Black 1, 20470: Stir 260 kg of 4-nitroaniline with 1200 L of water and a 23 % solution of 132 kg sodium nitrite for about 1/2 h. Run this suspension into a mixture of 4000 L water, 530 L 31 % hydrochloric acid, 500 kg ice, and a 23 % solution of 1.2 kg sodium nitrite at no more than 10 °C. Add about 1000 kg of ice and then 2600 L of an aqueous solution of 485 kg H acid within a period of 1 – 2 h with thorough stirring. Coupling is complete at the end of 3 h.

Meanwhile diazotize 165 kg of aniline in 300 L water, 1500 kg ice, and 440 L 31 % hydrochloric acid by adding 124 kg of sodium nitrite as a 23 % solution. This yields a volume of 3000 L. Then dissolve the monoazo dye by adding 360 L of 30 % sodium hydroxide solution and cool with about 3000 kg of ice. To this run in the solution of diazotized aniline and then immediately 1800 L of 15 % soda solution within 2 – 3 min. The volume is 22000 – 23000 L. After 6 h add common salt (9.5 % calculated on the volume) to cause salting out and continue stirring overnight. Filter off the precipitated dye and dry; the yield is about 1900 kg.

Usually the acid coupling of 4-nitroaniline is not continued to completion, because this requires too much time. Consequently, the commercial product normally contains a small proportion of red monoazo dye, which together with the greenish black disazo dye yields the desired neutral black shade.

Primary Disazo Dyes of the Type $K_1 \leftarrow D \rightarrow K_2$ ($K_1 = K_2$ or $K_1 \neq K_2$). This series includes many milling dyes because of the molecular size achieved (cf. Table 1, group C). Depending on the type of coupling components K_1 and K_2, which may be phenols, pyrazolones, acetoacetic acid arylamides, or naph-

tholsulfonic acids, clear yellow to red shades are obtained. The preferred diazo components are diaminodiphenyl derivatives and similarly structured diamines. Once important dyes derived from unsubstituted benzidine are now of no further importance because of the latter's carcinogenic activity (→ Benzidine and Benzidine Derivatives). Because the coupling of bisdiazotized diamines to form monoazo and disazo dyes proceeds with different rates, asymmetrical disazo dyes are readily manufactured. For example, the milling and wetfast red wool dye *C. I. Acid Red 114,* 23635 (**40**) [*6459-94-5*], is manufactured by coupling bisdiazotized 3,3′-dimethylbenzidine with one equivalent of Gacid; the monoazo compound obtained is further coupled with phenol to yield the disazo dye, the *p*-hydroxyl group of which is subsequently esterified with toluenesulfonic acid to improve the fastness properties and pH stability.

40

An important discovery was the realization that benzidines substituted in the 2,2′-position are outstandingly suitable for the manufacture of very wash-fast and milling-fast wool dyes, while the substantivity toward cellulosic fibers is reduced. A number of important acid wool dyes have been developed on this basis, for example, *C. I. Acid Yellow 44,* 23900 (**41**) [*2429-76-7*].

41

In the manufacture of this dye bisdiazotized 5,5′-dimethylbenzidine-2,2′-disulfonic acid is coupled to two equivalents of *N*-acetoacetylaniline. The clear, intense, greenish yellow dyeing obtained on wool is milling fast and exhibits excellent wetfastness but only moderate light fastness.

Other members of this series are *C. I. Acid Orange 56,* 22895:

benzidine-2,2′- ⟶ 1-phenyl-3-methyl-5-pyrazolone disulfonic acid ⟶2-naphthol

and *C. I. Acid Yellow 42,* 22910 [*6375-55-9*]

benzidine-2,2′- ⟶ 2 equivalents of 1-phenyl-3-methyl-disulfonic acid ⟶ 5-pyrazolone

Instructions for manufacturing C. I. Acid Yellow 42, 22910: Dissolve 250 kg of benzidine-2,2′-disulfonic acid in 2500 L of water at 50 °C that was made weakly alkaline with about 90 kg of soda. Then add 100 kg of sodium nitrite in the form of a 30 % solution. Run the entire solution into 4000 L of water at 25 °C, containing 350 L 31 % hydrochloric acid and 675 kg rock salt. The total volume is 7500 L, the temperature 30 °C. Stir for about 15 min during the diazotization process.

In the coupling vat add 264 kg of 1-phenyl-3-methyl-5-pyrazolone to 2000 L of water containing 80 kg of soda and dissolve at 80 °C. Then add another 80 kg of soda and cool with 2000 kg of ice to 20 °C. Run in the diazonium salt solution in about 30 min; no diazo reaction should occur during this procedure. Stir overnight, during which coupling takes place. Then draw off the dye and dry; the yield is about 720 kg.

In addition to benzidine derivatives another class of substances of interest as bifunctional diazo components consists of special diamines that can be manufactured through the reaction of aromatic amines with benzaldehyde or cyclohexanone, e.g.:

R = H, CH_3, OCH_3

Dyes based on these compounds possess, in addition to good light fastness, excellent wetfastness and are usually neutral dyeing on wool. This, although of no importance for dyeing pure wool, plays an important role in dyeing blended spun yarn and blended fabrics of wool and cotton or wool and viscose staple. The neutral dyeing acid dye can be used in combination with direct dyes (union wool recipes). Examples are *C. I. Acid Yellow 56,* 24825 (**42**) [*6548-24-9*],

42

and *C. I. Acid Red 154,* 24800 (**43**; R = CH_3) [*6507-79-5*].

43

*C. I. Acid Red 134,*24810 (**43**; R = OCH_3) [*6459-69-4*], is another interesting dye for wool and polyamide.

Particularly good milling fastness is achieved by the introduction of 4,4′-diaminodiphenylthioether as the diazo component, for example in the yellow wool dye *C. I. Acid Yellow 38,* 25135 (**44**) [*13390-47-1*].

44

Secondary Disazo Dyes. The secondary disazo dyes, which can be manufactured by series coupling according to the scheme D → M → K (D = diazo component; M = middle component; K = coupling component), offer much greater possibilities for variation than the primary disazo dyes. This group includes red dyes and, above all, important navy blues and blacks. Some of the red dyes of this type are manufactured from aminoazobenzene, aminoazotoluene, or the corresponding sulfonic acids by diazotization and coupling to naphtholsulfonic acids.

One of the oldest disazo dyes is Sudan IV, *C. I. Acid Red 66,* 26905 (**45**) [*4196-99-0*], which today is scarcely of any importance.

45

A product with a similar structure is *C. I. Acid Red 73,* 27290 (**46**) [*5413-75-2*], which is important today in wool dyeing and in paper coloration and leather dyeing because of its outstandingly clear shade and good leveling power.

46

The most important dyes of the type D → M → K are, however, black and navy blue wool dyes, which contain as the middle component M chiefly 1-naphthylamine or 1-naphthylamine-7-sulfonic acid and as the coupling component K *N*-phenylperi acid [= (1-phenylamino)naphthalene-8-sulfonic acid], *N*-tolylperi acid, and naphthol or 1-naphthylamine derivatives.

Examples of these high-yield and very washfast and lightfast dyes are *C. I. Acid Black 24,* 26370 (**47**) [*3071-73-6*], which is manufactured by coupling diazotized 1-naphthylamine-5-sulfonic acid to 1-naphthylamine, further diazotization of the aminomonoazo dye and coupling to *N*-phenylperi acid; and *C. I. Acid Blue 113,* 26360 (**48**) [*3351-05-1*]. This blue dye is very important in the dyeing of wool and polyamide.

47

48

Manufacturing instructions for C. I. Acid Blue 113, 26360: Dissolve 250 kg of 100 % aniline-3-sulfonic acid in about 3000 L of neutral water, add about 1000 kg of ice and 400 L of 31 % hydrochloric acid, and diazotize at 10 °C with a 23 % solution of 100 kg sodium nitrite. Then dissolve 220 kg 100 % 1-naphthylamine in 2000 L water with 185 L 31 % hydrochloric acid at the boil. Quickly run the solution into the diazotized aniline-3-sulfonic acid to which 4000 kg of ice has been added. Then in about 45 min partly neutralize to about pH 4 with 400 L of 15 % sodium

hydroxide solution, temperature 10 °C, volume of 15000 L. After adding 25 % by volume rock salt, stir for 2 h and again add 360 L of 15 % sodium hydroxide solution.

After cooling to 0 °C with about 1000 kg of ice, add 120 kg of sodium nitrite as a 23 % solution and then quickly 600 L of 48.5 % sulfuric acid. After 4 h separate the diazonium salt of the aminomonoazo dye in a filter press and stir the press cake into 1500 L of water and 400 kg of ice.

Dissolve 438 kg of 100 % *N*-phenylperi acid in 2000 L of water at about 80 °C and then adjust to a volume of 8500 L and a temperature of 10 °C with about 1500 kg of ice and water. Finally add 230 L of 15 % sodium acetate solution and adjust to pH 3 – 4 with about 10 L of 31 % hydrochloric acid. Then simultaneously feed into this solution 400 L of 15 % sodium acetate solution and the suspension of the diazonium salt press cake. Stir thoroughly and adjust this dispersion to the alkaline range by adding 250 L of 30 % sodium hydroxide solution and cause to dissolve by heating to 80 °C. Add 10 % by volume rock salt and continue stirring for 3 h. Separate the dye in a filter press at 70 °C. The final volume is 19000 L; the yield is 800 kg of dried product.

A very wash-fast black wool dye is *C. I. Acid Black 26,* 27070 (**49**) [*6262-07-3*].

49

It contains 4-amino-diphenylamine-2-sulfonic acid as the diazo component, 1-naphthylamine as the middle component, and 2-naphthol-6-sulfonic acid as the final coupling component.

3.2.1.3. Chrome Dyes [3, p. 464], [15, p. 680]

Azo dyes with certain groupings can be converted on the fiber with chromium salts to chromium complexes that are more or less soluble (see Section 2.3.4). This "chroming" of largely acid monoazo dyes improves the light fastness of the dyeings and above all their wet-fastness, because the complex formation blocks the hydrophilic groups in the molecule. It also results in a deepening and dulling of the shade, so that these dyes do not yield brilliant colors. Consequently, for combination dyeing the range of chrome dyes has been supplemented with brilliant acid dyes, which cannot form chrome lakes and survive the chroming process without change.

Chrome dyes are applied to the fiber chiefly with the aid of the afterchroming method and special products also by the one-bath chroming method (metachrome process). For ecological reasons chrome dyes are of severely limited importance.

Dyes for the Afterchroming Method. In afterchroming the dye is allowed to go onto the fiber from an acid bath, and this is followed by treatment with dissolved alkali dichromate, which is reduced by the cystine group of the wool to trivalent chromium compounds. The chromium complex formed on the wool fiber contains two azo dye radicals for each metal atom (1 : 2 complex compound).

In the reversal of this process with so-called mordant dyes, first the chromium salt is applied to the fiber (premordanting) and then the dye. Mordant dyeing is essentially only of historical interest.

The afterchroming dyes have lost their former importance because of the considerable amount of time required by the dyeing process, but they are still used in wool dyeing because of their low price. For the names of important afterchroming dye ranges see Table 2.

Table 2. Important ranges of afterchroming dyes

Manufacturer	Range
Bayer	Diamantchrom
Ciba-Geigy	Eriochrom
Sandoz	Omegachrom

Furthermore, dyes of this type are still produced in large amounts in the COMECON countries and in the People's Republic of China.

In the yellow and orange types the salicylic acid grouping dominates. One of the most important chrome-developed yellow dyes is *C. I. Mordant Yellow 1,* 14025 (**50**) [*584-42-9*]. After chroming it yields a somewhat dull yellow with good fastness properties.

50

51

C. I. Mordant Yellow 5, 14130 (**51**) [*6054-98-4*], possesses two salicylic acid groups. After chroming the product is greenish yellow and exhibits very good general fastness properties. Because diazotized aminosalicylic acid is not sufficiently electrophilic, the dye is manufactured by coupling diazotized 5-amino-2-chlorobenzoic acid to salicylic acid and saponifying the activated chlorine atom.

The complex formation on the salicylic acid group has little influence on shade and light fastness, in contrast to *o,o′*-disubstituted arylazo compounds, on which complexing brings about a considerable deepening of shade and usually marked increase in light fastness. Examples: *C. I. Mordant Red 7,* 18760 (**52**) [*3618-63-1*], dyes wool a dull orange, which through chroming becomes a clear red with very good fastness properties.

52

Red, blue, and primarily black afterchroming dyes contain naphthalene radicals in the diazo or coupling component.

A blue dye, for example, is *C. I. Mordant Blue 13,* 16680 (**53**) [*1058-92-0*].

53

One of the most important black dyes is *C. I. Mordant Black 9,* 16500 (**54**) [*2052-25-7*].

54 55

Oxidation of the dye during chroming with dichromate creates a naphthoquinone structure in the molecule (**55**). Two other important black dyes are *C. I. Mordant Black 3,* 14640 (**56**, R = H) [*3564-14-5*], and *C. I. Mordant Black 11,* 14645 (**56**, R = NO_2) [*1787-61-7*].

56

C. I. Mordant Black 11 is also used as an indicator in the complexometric titration of various bivalent metals with which the dye forms complexes [24].

The *o,o′*-dihydroxyaminoazo and *o*-hydroxy-*o′*-aminoazo compounds with phenols or aniline derivatives as coupling components yield largely brown shades on chroming; they include one of the most important brown dyes with very good fastness properties, *C. I. Mordant Brown 33,* 13250 (**57**) [*3618-62-0*].

57

The rarely used chrome-developed disazo dyes mostly contain the salicylic acid grouping, which in the type D → M → K (see page 27) is usually introduced into the molecule in the form of aminosalicylic acid as the diazo component. Dyes of the type $K_1 \leftarrow D \rightarrow K_2$ (see page 25) are manufactured by coupling bisdiazotized benzidine derivatives (D) to two equivalents of salicylic acid ($K_1 = K_2$) or to one equivalent each of salicylic acid (K_1) and naphtholsulfonic acid (K_2).

Dyes for the One-Bath Chroming Method (Metachrome Process). In this method the metal complex is formed on the fiber by the simultaneous action of chrome dye and dichromate. Compared with the afterchroming method metachrome dyeing has the advantage of simpler application, but the number of usable dyes for this process is more severely limited. Whether a dye is suitable for the metachrome process depends on its hydrophilic character and its rate of complex formation [15, p. 680].

The method is used at present for wool dyeing primarily because of price considerations.

Examples of typical one-bath chroming dyes are: *C. I. Mordant Yellow 30,* 18710 (**58**) [*10482-43-6*], *C. I. Mordant Red 19,* 18735 (**59**) [*1934-24-3*], *C. I. Mordant Red 30,* 19360 (**60**) [*6359-71-3*], *C. I. Mordant Brown 48,* 11300 (**61**) [*6232-53-7*], and *C. I. Mordant Blue 7,* 17940 (**62**) [*3819-12-3*].

3.2.1.4. Metal-Complex Dyes

(cf. Section 2.3.4)

Only a short overview of the subject will be given here (for detailed treatment → Metal-Complex Dyes). Metal-complex dyes are manufactured in the complete dye form before the dyeing process and usually contain chromium or cobalt ions, rarely copper or iron ions, bound in the molecule. A distinction is made between 1 : 1 and 1 : 2 metal-complex dyes, depending on whether there is one metal ion for each dye molecule or for every two dye molecules. These products generally yield dyeings of high light and wetfastness but of somewhat muted shades.

1 : 1 Metal-Complex Dyes. Among these dyes primarily the 1 : 1 chromium complexes containing sulfonic acid groups have achieved commercial importance. They must be applied from a strongly acid bath, which imposes certain limits on their range of applications. The 1 : 1 metal complexes are not suitable for polyamide, which is partially decomposed under the dyeing conditions for these products. Their main area of application is in the dyeing of wool, but they are also suitable for leather dyeing. See Table 3 for a list of ranges.

Table 3. Important ranges of 1 : 1 metal-complex dyes

Manufacturer	Range
BASF	Palatin Fast
Ciba-Geigy	Neolan

The 1 : 1 metal-complex dyes are also produced in large amounts in the COMECON countries and in the People's Republic of China; manufacturers in, for example, India or Greece are of lesser significance.

The manufacture of 1 : 1 chrome complex dyes takes place in two operations: manufacture of the azo dye capable of chrome development and formation of the chromium complex. Similarly as for the one-bath chroming dyes, negatively substituted *o*-aminophenols but also *o*-aminonaphthols and their sulfonic acids are used as diazo components; 2-naphthol, 2-naphtholsulfonic acids, pyrazolones, acetoacetic acid aryl amides, and 2,4-dihydroxyquinoline serve as the coupling components.

1 : 2 Metal-Complex Dyes. Because of their complexed structure 1 : 2 metal-complex dyes exhibit anionic character. Those which have gained commercial importance are primarily the ones that are free of sulfonic acid groups and for which adequate water solubility is provided by nonionic, hydrophilic substituents, such as methylsulfone or sulfonamide groups [15, p. 689], [25].

The introduction of 1 : 2 metal-complex dyes, which are applied from a neutral to weakly

acid bath, represented a significant technical advance over the strong-acid-dyeing 1 : 1 chrome complex dyes. It has meant better protection of the fiber material, simplification of the dyeing process, and improvement of the fastness properties.

Because these dyeings, like all metal-complex dyeings, usually exhibit subdued shades, the 1 : 2 metal-complex dyes are combined with small amounts of acid dyes or suitable reactive dyes to brighten the tint.

Owing to their outstanding wetfastness, high light fastness, and good fiber levelness, the 1 : 2 metal-complex dyes are of major importance in dyeing wool and polyamide. Important ranges of these dyes are listed in Table 4.

Table 4. Important ranges of 1 : 2 metal-complex dyes

Manufacturer	Range
BASF	Ortolan
Bayer	Isolan
Ciba-Geigy	Irgalan
Sandoz	Lanasyn

The extent of variation is extremely large as a result of the great number of available diazo and coupling components, the choice of complex-forming metal (primarily chromium or cobalt), and the possibility of synthesizing 1 : 2 metal mixed complexes.

Substituted *o*-aminophenols and also anthranilic acid and its derivatives are the most important diazo components. The main coupling components are pyrazolones, acetoacetic acid arylamides, naphthols, N-substituted aminonaphthols, and naphthylamines.

For subdued shades the 1 : 2 metal-complex dyes with one or two sulfo groups continue to play an important role. Dyes with one such group contain the sulfonic acid group in one of the two parts bound to the azo group and complexed to chromium or cobalt. They are built up stepwise via the 1 : 1 metal-complex. Compared with the 1 : 2 metal-complex dyes with nonionic hydrophilic groups they exhibit better solubility in water but poorer leveling power, and therefore they are always used together with specially selected leveling auxiliaries. The ranges of these dyes (Table 5) contain primarily navy blue, black, dark brown, and olive shades.

Table 5. Important ranges of 1 : 2 metal-complex dyes containing monosulfonic and disulfonic acid groups

Manufacturer	Range
BASF	Acidol M
Bayer	Isolan S
Ciba-Geigy	Lanacron S
Hoechst	Azarin
ICI-Francolor	Neutrichrom S
Sandoz	Lanasyn S

The 1 : 2 metal-complex dyes with two sulfonic acid groups are a more recent development.

Contrary to the opinion frequently expressed in the literature that such dyes would exhibit inadequate levelness when applied in a weakly acid bath and inadequate stability to acid in a strongly acid dyebath, they are very well suited for dyeing wool and polyamide if certain pH conditions are observed. These products are very soluble in water, have high tinctorial strength, and are very high-yield dyes with a relatively simple structure (for further details → Metal-Complex Dyes).

3.2.2. Polyamide Dyes [5, vol. III, p. 276]

Synthetic polyamides have a structure similar to those of wool and silk but differ in having a low acid-binding power and in their capacity to dissolve nonpolar compounds. In consequence materials of polyamide can be dyed with disperse dyes as well as with selected acid dyes, including metal-complex dyes.

When choosing *acid dyes* for polyamides it must be borne in mind that owing to the lower acid-binding power dyes with two and more sulfonic acid groups in the molecule go onto the fiber much more slowly and to a much lower saturation value than dyes with one sulfonic acid group. Consequently, these dyes cannot be mixed or combined with one another, which has been taken into account in composing the product ranges.

Since acid dyes on polyamide behave as they do on wool in regard to leveling power, build-up, and fastness properties (see Section 3.2.1), they fall into two classes (cf. Table 6):

Group A: acid dyes with good leveling power and low substantivity for polyamide; they yield dyeings with reasonably good wetfastness.

Group B: acid dyes with lower leveling power, higher substantivity and high wetfastness standard on polyamide. Many of these acid dyes with a lower leveling power rather clearly reveal differences in fiber structure that may result from, for example, differences in the degree of drawing (so-called streakiness), so that it is usually necessary to add leveling and retarding auxiliaries (→ Textile Dyeing).

Table 6. Important ranges of polyamide dyes

Manufacturer	Range	
	Group A	Group B
BASF	Acidol	Acidol
Bayer	Telon Supra	Telon Fast
Ciba-Geigy	Erionyl Tectilon	Erionyl
Crompton & Knowles	Nylanthrene	Nylanthrene
ICI	Nylomine A Nylomine B	Nylomine C
Sandoz	Nylosan E	Nylosan F Nylosan N

The main area of application for the acid polyamide dyes characterized in group A is in carpet dyeing, but they are also used in other areas of textile dyeing where the fastness requirements are not too stringent. A few structures are presented below to illustrate the types of azo dyes used: *C. I. Acid Yellow 25,* 18835 (**63**) [*6359-85-9*], *C. I. Acid Orange 67,* (**64**) [*12220-06-3*], *C. I. Acid Red 42,* 17070 (**65**) [*6245-60-9*], *C. I. Acid Red 32,* 17065 (**66**) [*6360-10-7*].

63

64

65

66

Group B dyes are used almost exclusively for clothing textiles for which more stringent requirements are placed on wetfastness. Some of the typical azo dyes of this type are *C. I. Acid Yellow 42*, 22910 (**67**) [*6375-55-9*], *C. I. Acid Yellow 65,* 14170 (**68**) [*6408-90-8*], *C. I. Acid Red 114,* 23635 (**69**) [*6459-94-5*], *C. I. Acid Blue 113,* 26360 (**70**) [*3351-05-1*].

67

68

69

70

Other acid disazo dyes for polyamide are secondary disazo dyes (D → M → K) with one or two sulfonic acid groups bound to aromatic nuclei or with an external sulfate group, which is situated mainly in the diazo component D. Aniline, 1-naphthylamine, and their derivatives preferably serve as the middle component M, whereas the coupling components of the phenol and arylamine series common in disperse dyes are used as the final hydrophobic component K [26–30], as illustrated by the general structure **71**.

71

R^1 and R^2 = alkyl groups, partially substituted

The patent literature indicates that polyamide dyes of this type are generally characterized by high tinctorial strength and light fastness and a good capacity to compensate for nonuniformity in the material.

Because of increasing standards of wetfastness, lightfast *reactive dyes* are also being used in polyamide printing, especially to produce pastel shades. However, only selected representatives of the cotton reactive dyes so far offered on the market are suitable for polyamide. Essentially the products recommended for polyamide contain monosulfonic and disulfonic acid groups with β-sulfatoethylsulfone, α-bromoacrylamide, α,β-dibromopropionylamide, monochlorodialkylaminotriazine, and trihalopyrimidyl groups, particularly 2,4-difluoro-5-chloropyrimidyl groups (→ Reactive Dyes).

Because of their high fastness standards the *1 : 2 metal-complex dyes* have also acquired some importance in the dyeing of polyamide. They are used primarily in the clothing sector to achieve deep shades. The first complete range of these dyes for polyamide fibers was developed in 1940 – 1943 at the Ludwigshafen works of the then I. G. Farbenindustrie, but owing to the events of the day they never reached the market. The range consisted of dyes with and without nonionic, hydrophilic groups.

Later these dye types were further developed by other companies and uniform ranges were placed on the market. Dyes with nonionic, hydrophilic groups are offered for wool and polyamide dyeing (see page 30), while the use of water-insoluble 1 : 2 metal-complex dyes is restricted to polyamide dyeing; Table 7 shows ranges of these products. In a process comparable to disperse dyeing, these dyes are applied to polyamide from a finely dispersed aqueous suspension and yield extremely lightfast and wetfast dyeings (for further details → Metal-Complex Dyes).

Table 7. Important ranges of dispersed 1 : 2 metal-complex dyes

Manufacturer	Range
BASF	Vialon
Ciba-Geigy	Avilon
ICI-Francolor	Amichrom

3.2.3. Silk Dyes

Because natural silk, as a protein fiber of animal origin, resembles wool fiber in its chemical structure, it can be dyed with nearly all the classes of dyes used for wool. The choice of dyes depends essentially on the fastness properties required.

Of great importance for the dyeing of natural silk are selected members of the class of acid wool dyes (see Section 3.2.1). The occasionally inadequate wetfastness of these dyeings can be substantially improved by the proper aftertreatment (e.g., with potassium sodium tartrate and tannin).

Selected acid 1 : 1 chrome complex dyes, because of their good wetfastness and light fastness and their very good leveling power, and also 1 : 2 chrome complex and 1 : 2 cobalt complex dyes with hydrophilic groups (see page 30) have successfully come into use as silk dyes.

Furthermore, direct dyes (see Chap. 4) are among the most important silk dyes. Their fastness properties can be improved by aftertreatment with metallic salts or formaldehyde.

If suitably selected, cationic dyes (see Chap. 5) can also be used for dyeing weighted silk, toward which they exhibit special affinity, in addition to having good leveling power and very good wetfastness. On the other hand, the light fastness of these dyeings is not always satisfactory.

Reactive dyes have also found a place in silk dyeing. These dyeings are characterized by very fast and bright shades with exceptionally good wetfastness.

Initially the development of synthetic fibers greatly reduced the importance of silk dyeing. The processing of silk has undergone a marked increase owing to the growing quality consciousness of buyers, who appreciate the outstanding wear properties of silk, and because of the intensified activities of China on the world market.

In addition to China the countries that are still prominent in silk processing today are Japan and Italy.

3.2.4. Leather Dyes

Leather is produced by tanning skins of different origin and the tanning process has a decisive influence on the dyeability of the pretreated products. The differences in the dyeing behavior of leather of various origins that has been tanned in different ways are about as marked as those of the different textile fibers.

Many of the anionic, cationic, metal-complex, and direct dyes employed in the textile field are also used for dyeing leather. In addition ranges have been developed that are particularly suitable for dyeing leather. The choice of dye depends largely on the tanning method, the fastness properties required, and the end use, and a distinction is made, depending on the depth of penetration of the dyes, between surface dyeing, part-penetration dyeing, and full-penetration dyeing (for more details on the dyeing of leather → Leather).

The main shades used are different browns and blacks, as well as bordeaux, reds, yellows, blues, and greens. Most of the leather dyes belong to the azo class. They are marketed both as individual dyes and in the form of mixtures. The most important ranges are listed in Table 8. Because of the many different classes of dyes used, several ranges are available:

Group A includes both anionic and direct dyes. They are used mainly for dyeing chrome leather and alum-tanned glove leather. The basic difference between acid and direct dyes, which is pronounced in textile dyeing, is less marked in the dyeing of leather. Therefore, the two groups often tend to be combined under the term "anionic dyes". The dyeings obtained have good light fastness and good to very good wetfastness, rub fastness, and fastness to washing.

Group B contains acid 1 : 1 chrome-complex dyes as well as 1 : 2 chrome- and 1 : 2 cobalt-complex dyes with hydrophilic groups (see Section 3.2.1.4). Particularly stringent demands can be made on these dyes in terms of light, wet, and perspiration fastness and leveling properties. Some of the ranges used here are already familiar from the textile field.

Group C is composed of acid dyes and direct dyes. Unlike group A, they are mainly dye mixtures that give marked coloration of the leather as well as good surface coverage.

Group D consists of pigment preparations that are important for the treatment of leather and are applied by different methods (spraying, padding, curtain coating). The ranges contain both organic and inorganic pigments and mixtures of the two. They are marketed as binder-containing or binder-free, finely dispersed aqueous pigment preparations and have high covering power and in most cases very good light fastness.

The large number of *cationic* dyes suitable for dyeing leather cannot be grouped under one specific range. They have very good covering power and give a high yield and brilliant shades. Their light fastness is generally only moderate. They are used for vegetable tanned leathers and as a so-called top dyeing for chrome leather.

To obtain the good fastness to buffing that is particularly important in the dyeing of suede, special dyes are used which, in addition to adequately deep and level surface dyeing, also give good penetration so that no change in shade occurs when the leather is subsequently buffed.

Some typical *anionic* azo dyes for leather are: *C. I. Mordant Brown 33,* 13250 (**72**) [*3618-62-0*]: strong penetration, poor coverage;

72

C. I. Acid Brown 105, 33530 (**73**) [*8003-78-9*]: poor penetration, good coverage;

73

C. I. Acid Black 24, 26370 (**74**) [*3071-73-6*]: no penetration, good coverage;

3.2.5. Azo Food Dyes

In terms of quantity and value food dyes play only a relatively minor role in the dye-making industry.

A brief survey is given here of the azo dyes that have been approved for food coloration. For a detailed treatment of the subject, including legislation and official regulations, → Foods, 3. Food Additives.

From the chemical viewpoint some of the most frequently used synthetic food dyes belong to the azo series.

The dyes approved for food coloration in the EEC are listed in the guidelines for colorants of 23. Oct. 1962, which are continually updated. The member states of the EEC must convert these guidelines to national law.

The azo dyes listed below bear, in addition to the L number of the Dye Commission of the Deutsche Forschungsgemeinschaft (DFG, German Research Association), an EEC number (E) under which they are registered in the EEC: *C. I. Food Yellow 4,* 19140, L-Yellow 2, E 102, Tartrazine, (**76**) [*1934-21-0*]

76

C. I. Food Yellow 3, 15985, L-Orange 2, E 110, Yellow Orange S, (**77**) [*2783-94-0*]

77

C. I. Food Red 9, 16185, L-Red 3, E 123, Amaranth S, (**78**) [*915-67-3*]

78

C. I. Food Red 7, 16255, L-Red 4, E 124, Ponceau 4 R, (**79**) [*2611-82-7*]

79

C. I. Food Red 3, 14720, L-Red 1, E 122, Azo Rubine, (**80**) [*3567-69-9*]

80

C. I. Food Black 1, 28440, L-Black 1, E 151, Brilliant Black BN, (**81**) [*2519-30-4*]

81

The use of dyes for pharmaceutical preparations is regulated in the EEC by guidelines from 1978 and 1981 and the Directive concerning Pharmaceuticals Dyes of 1982. Here practically the same dyes are permitted as for food.

For other areas of application different regulations apply. These regulations differ from one another in respect of the dyes permitted (for example, in the cosmetics sector the cosmetics guidelines and the Directive on Cosmetics).

The food dyes permitted in the USA are compiled in the Code of Federal Regulations, Vol. 21, Food and Drugs, Parts 1 to 99; continual amendments are published in the Federal Register.

A synthetic dye is permitted for dyeing food only if thorough toxicological studies reveal no danger of toxic effects to the consumer. Food dyes are among the food additives that have been subjected to the most thorough toxicological examinations.

Purity Requirements: Food dyes that are placed on the market must meet special purity requirements, which have been fixed by law for the Federal Republic of Germany in the Directive on Additives of 20. 12. 1977. According to this regulation the following substances must not be detectable in food dyes:Barium compounds that are soluble in dilute hydrochloric acid; cadmium, mercury, selenium, tellurium, thallium, uranium and chromates; polycyclic aromatic hydrocarbons with 3 or more fused nuclei; and 2-naphthylamine, benzidine, and 4-aminobiphenyl (xenylamine).

Upper limits have been specified for the following contaminants:

arsenic		max. 5 mg/kg
lead		max. 20 mg/kg
antimony, copper, chromium, zinc, barium sulfate	individually	max. 100 mg/kg
		max. 200 mg/kg
	together	
aromatic amines		max. 100 mg/kg
portions extractable with ethyl ether∗		max. 0.2 %
water-insoluble portions∗		max. 0.2 %

∗ Only in the dyes E 102 – 110, E 122 – 132, E 142 and E 154.

Furthermore, special purity requirements have been placed on individual dyes.

In the Federal Republic of Germany the analytical methods for testing the degree of purity have been published by the Dye Commission of the DFG.

In the USA the regulations for the purity of food dyes are specified in the Code of Federal Regulations. The Food and Drug Administration (FDA) is responsible for the registration and certification of food dyes.

4. Direct (Substantive) Dyes

Direct or substantive dyes are colored compounds that are mainly used to dye materials made from natural or regenerated cellulose (e.g., cotton, jute, viscose, or paper) without employing mordants as auxiliaries. The essential requirement for classification of a dye in this group is its substantivity, i.e., its absorption from an aqueous salt-containing solution onto cellulosic materials. Absorption onto cotton takes place in a neutral to soda alkaline medium and onto paper in a weakly acid to neutral medium.

Substantivity was initially attributed to secondary valence bonding between fiber and dye. The fact that coplanar molecules are always more substantive than nonplanar ones later led to the coplanarity theory with its assumption that coplanar dyes are in contact with the cellulose molecule along their entire length.

The presence of hydrogen bonds has also been expounded as a possible explanation for high affinity between fiber and dye [31]; however, such bonds are probably prevented by a water layer between fiber and dye [32].

The nature of substantivity has been very convincingly explained [33].

According to this explanation, single dye molecules are adsorbed by the intermicellary cavities of the cellulosic fibers and, unlike nonsubstantive dyes, they form aggregates in these cavities.

Because of their size, these aggregates can no longer be directly washed out with water, but only after further solvation has taken place.

Because direct dyes become aggregated in aqueous solutions at normal temperatures, substantivity often cannot take effect until the temperature has risen. Only then diffusion into the fiber is possible.

The tendency toward aggregation is therefore characteristic of substantive dyes, which also explains why coplanar dyes possess greater substantivity than nonplanar ones.

There is no exact delineation between substantive and nonsubstantive dyes, the boundaries between them are fluid.

Structural Characteristics. Azo dyes comprise the major proportion of the direct dyes; apart from these, only a few azine, phthalocyanine, and nonazo metal-complex dyes possess a certain significance. The following structural characteristics are necessary for high substantivity:

a) *Coplanarity of the Dye Molecules.* The importance of coplanarity is shown by the example of 4,4′-diaminodiphenyl derivatives. Whereas 3,3′-disubstituted diaminodiphenyls (e.g., *o*-tolidine or *o*-dianisidine) as diazo components produce high absorptive power in dyes, this substantivity is neutralized in 2,2′-disubstituted derivatives and coplanarity of these molecules is no longer possible.
b) *Long Chain of Conjugated Double Bonds.*Dye molecules of this kind (see also Schirm's rule [34]) can contain bridges, such as $-CH{=}CH-$, in addition to the aromatic rings, thus ensuring the development of resonance forms across the entire molecule. Exceptions to this rule are the bridges $-NHCONH-$, $-CONH-$, and $-NH-$, which increase substantivity in spite of the interruption in the conjugated system. In these groups, the ability to form hydrogen bonds is the decisive factor. Other groups causing an interruption in the conjugated system, e.g., $-CH_2-$, $-CH_2CH_2-$, $-CO-$, $-S-$, $-SO_2-$, and cyclohexylene, decisively lower substantivity. Only the substantivity of the linked segments remains.

On the basis of the structural characteristics described, direct dyes based on benzidine can be commended for their good substantivity. In fact this group was for a long time a significant constituent of all important direct dye ranges in the shade spectrum from red to brown, blue, green, and black.

Because of the carcinogenic properties of unsubstituted benzidine in humans about 15 – 20 years ago almost all major dye manufacturers in the most important western industrialized countries stopped production of dyes based on this substance.

This development led to an intensive search for substitute dyes, the results of which are reflected in particular in the patent literature. The significance of this development is also discernible in the number of direct dyes newly registered with the Colour Index between 1971 and 1982. The research efforts are especially apparent in the case of black, with 21 new registrations; yellow, brown, and blue, each with 19;

and red, with 17. However, of a total of 115 direct dyes, the constitution has as yet only been stated in 7 instances. It is therefore not possible to evaluate the patent literature results with regard to the industrial significance of the products.

Starting Compounds. Based on the requirements mentioned, the following starting compounds are especially suited for the synthesis of direct dyes:

a) 3,3′-Disubstituted 4,4′-diaminodiphenyl derivatives, but not 2,2′-disubstituted ones. These are, therefore, diamines with the structure

where $X = CH_3$, OCH_3, Cl, SO_3H. 1,4-Diaminophenyl derivatives also belong to this group.

b) Compounds of the type

where $X = NH$, SO_2, $-N{=}N-$, $-CONH-$, $-CSNH-$, $-SO_2NH-$, $-CH{=}CH-$, $-HNCONH-$, $-HNCSNH-$, $-O_2SNHSO_2-$.

c) 1,4-Diaminonaphthalene and 1,5-diaminonaphthalene

d) *m*-Phenylenediamine and other 1,3-disubstituted diamines, e.g., 2,6-diaminotoluene-4-sulfonic acid or bis(3-aminophenyl)urea.

e) Heterocyclic diamines

Because of their ease of application and moderate price, direct dyes still represent one of the largest groups of azo dyes, although their wetfastness, in particular, often only satisfies moderate to average requirements. The only slight decrease in consumption of direct dyes following the appearance of the wetfast reactive dyes is due to the markedly higher price of reactive dyes. For product ranges see Table 9.

Direct dyes are classified according to their method of application:

a) *Conventional Direct Dyes.* They include monoazo, disazo, trisazo, and tetrakisazo dyes. It is advantageous to subdivide them according to the nature of their chemical structure. Disazo dyes, for example, can be divided according to chemical synthesis principles into primary and secondary. Conventional azo direct dyes further include symmetric urea derivatives, dyes obtained by oxidation of amines, and triazinyl and copper-containing dyes.

b) *Direct Dyes with Aftertreatment.* This group includes direct dyes that after being applied to the fiber by the usual method undergo one of the following aftertreatments:
   Aftertreatment with cationic auxiliaries
   Aftertreatment with formaldehyde
   Diazotization of the dye on the fiber and coupling with suitable components (diazotization dyes)
   Aftertreatment with metal salts

4.1. Conventional Direct Dyes

4.1.1. Monoazo Dyes

Only a few monoazo dyes possess the necessary substantivity to render them suitable for direct dyeing of cellulosic fibers.

Of practical importance as diazo components are only the derivatives of 2-(4′-aminophenyl)-6-methylbenzthiazole, of the so-called dehydrothio-*p*-toluidine (**82**):

82

Table 9. Designations of important ranges of direct dyes (The names in brackets are the U.S. products of the relevant Western European company)

Manufacturer	Product range
Western Europe	
BASF (FRG)	Lusantin, (Phenamine)
Bayer (FRG)	Benzamin, Benzo, Benzocuprol, Sirius, Sirius Supra
Ciba-Geigy (Switzerland)	Cuprophenyl, Diphenyl, Solophenyl, (Diazophenyl)
Croda (United Kingdom)	Covazol, Diazin
Hoechst/Cassella (FRG)	Cotonerol, Diamin, Duasyn, (Rayon)
ICI (United Kingdom)	Chlorazol, Durazol
PCUK/ICI (France)	Cuprodiazol Light, Diazamine, Diazol, Diazol Fast, Diazol Light, Metadiazol
Rovira (Spain)	Hispadiazo, Hispaluz, Hispamin

Sumitomo	Direct, Japanol, Nippon, Sumilight, Sumilight Supra

The compound **82** is obtained by melting *p*-toluidine with sulfur at 130 – 230 °C. The derivatives (**83**) – (**86**) are used to produce monoazo direct dyes:

83

Dehydrothio–p–toluidine–sulfonic acid

84

Dehydrothio–p–toluidine–disulfonic acid

85

Primulin base

86

Whereas **83** and **84** are obtained by sulfonation of dehydrothio-*p*-toluidine (**82**) with oleum, compounds **85** and **86** are formed in a mixture with **82** during the sulfur melting process and are separated by vacuum distillation.

Acetoacetic acid arylides and pyrazolone derivatives are the coupling components mainly used. Naphtholsulfonic acids are of only minor importance here. Dehydrothio-*p*-toluidinesulfonic acid (**83**) and the sulfonated primulin base are also used as diazo components for certain orange disazo direct dyes.

Examples. Diazotization of dehydrothio-*p*-toluidinesulfonic acid (**84**) and coupling to acetoacetic acid *o*-anisidide results in the lightfast yellow *C. I. Direct Yellow 27,* 13950 (**87**) [*10190-68-8*].

87

Coupling the diazotized monosulfonic acid of the primulin base to acetoacetic acid anilide produces the clear, greenish yellow *C. I. Direct Yellow 22,* 13925 (**88**) [*10190-69-9*].

88

Substantive yellow monoazo dyes with very good light fastness are also obtained by oxidation of dehydrothio-*p*-toluidine and its deriva-

89

tives (see Section 2.2.3). Oxidation of the sodium salt of the monosulfonic acid of the primulin base in the alkaline pH range with sodium hypochlorite results, for example, in *C. I. Direct Yellow 29,* 19556 (**89**) [*6537-66-2*].

As with the corresponding oxidation of dehydrothio-*p*-toluidinesulfonic acid (**83**), which results in *C. I. Direct Yellow 28,* 19555 (see Section 2.2.3), in addition to the azo dye, diphenazines (**90**) are obtained as byproducts, e.g., which in some cases have to be separated

90

when they impair the shade and fastness properties of the dyes.

4.1.2. Disazo Dyes

4.1.2.1. Primary Disazo Dyes

Primary disazo dyes are obtained in accordance with the pattern $K_1 \leftarrow D \rightarrow K_2$ by bisdiazotization of a bifunctional diazo component D and coupling to two equivalents of coupling component K_1 and K_2, or according to the pattern $D_1 \rightarrow K \leftarrow D_2$ by coupling of two equivalents of diazo component (D_1 and D_2) to one equivalent of a bifunctional coupling component. Depending on whether K_1 and K_2 or D_1 and D_2 are the same or different, symmetrical or asymmetrical dyes are obtained.

Type $K_1 \leftarrow D \rightarrow K_1$ *Primary symmetrical disazo dyes* with benzidine as bisdiazo component were long considered to be the prototype of direct dyes. Development of this dye class commenced with congo red, *C. I. Direct Red 28,* 22120 (**91**) [*573-58-0*].

91

Both as regards the number of products on the market and the consumption in terms of volume, the disazo dyes of the bisdiazotized benzidine were for a long time the most important substantive dyes. Today, no individual chemical group enjoys such significance. Instead, besides the substituted 4,4′-diaminodiphenylene, several other groups, including heterocyclicones, have taken the place of benzidine.

o-Dianisidine as bisdiazo component has a certain significance in blue direct dyes of the congo red type. Coupling with two equivalents of H acid results in *C. I. Direct Blue 15,* 24400 (**92**) [*2429-74-5*].

92

With chromotropic acid (1,8-dihydroxynaphthalene-3,6-disulfonic acid) as coupling component, *C. I. Direct Blue 10,* 24340 [*4198-19-0*], is obtained (see page 41).

A very clear pure blue is obtained through the alkaline coupling of bisdiazotized *o*-dianisidine to two equivalents of Chicago acid SS (1-amino-8-hydroxynaphthalene-2,4-disulfonic acid): *C. I. Direct Blue 1,* 24410 (**93**) [*2610-05-1*].

93

o-Tolidine is also occasionally encountered as diazo component, e.g., in *C. I. Direct Blue 14,* 23850 (**94**) [*72-57-1*].

94

The dye enjoyed major significance and in addition was one of the first chemotherapeutics to be used as a remedy for protozoal diseases (Trypan Blue).

Other important diamines used for the synthesis of symmetrical substantive disazo dyes are 4,4′-diaminostilbene-2,2′-disulfonic acid (**95**) and 4,4′-diaminodiphenylurea-3,3′-dicarboxylic acid or -3,3′-disulfonic acid (**96**):

95

96

X = COOH or SO_3H

The diamine **95** is obtained by heating 4-nitrotoluene-2-sulfonic acid in diluted sodium hydroxide solution with sodium hypochlorite, 4,4′-dinitrostilbene-2,2′-disulfonic acid being formed in the process, and subsequent reduction with iron and hydrochloric acid. Compounds **96** can be produced from 4-nitroaniline-2-carboxylic acid or -2-sulfonic acid by treatment with phosgene and subsequent reduction. The sodium salt of 4,4′-dinitrostilbene-2,2′-disulfonic acid itself belongs to the group of stilbene dyes. It is mainly used as *C. I. Direct Yellow 11,* 40000 [*1325-37-7*] for the coloration of paper.

Stilbene dyes are different self-condensation products of 4-nitrotoluene-2-sulfonic acid produced with of sodium hydroxide solution. The various types are synthesized depending on the concentration of sodium hydroxide, the reaction temperature, and the reaction time. In some cases a subsequent reaction with arylamines is carried out.

An example of the combination with **95** is *C. I. Direct Yellow 12,* 24895 (**97**) [*2870-32-8*], also known as chrysophenine:

97

The product is obtained by coupling bis-diazotized 4,4′-diaminostilbene-2,2′-disulfonic acid with two equivalents of phenol and subsequent ethylation. It is a very high-strength reddish yellow with very good leveling power and average fastness properties, which is excellently suited for the dyeing of fabric blends, e.g., cotton – polyamide. For manufacturing specifications see below.

An example of the use of **96** as diamine is *C. I. Direct Red 75,* 25380 (**98**) [*2829-43-8*].

98

Other direct dyes with the diphenylurea group can be produced from aminomonoazo dyes by subsequent treatment with phosgene (see Sections 2.3.2 and 4.1.6).

Type $K_1 \leftarrow D \rightarrow K_2$ *Primary Asymmetrical Disazo Dyes.* Since the coupling reactions of substituted 4,4′-diaminodiphenylene to monoazo or disazo dye proceed at different rates, asymmetrical coupling reactions can be carried out. The first (acid coupling) proceeds from bis-diazotized *o*-dianisidine with one equivalent of a coupling component to a monoazo intermediate compound, which now together with a second (different) coupling component forms an asymmetrical disazo dye.

Example: *C. I. Direct Blue 22,* 24280 (**99**) [*2586-57-4*], is obtained by coupling *o*-dianisidine to Chicago acid SS and β-naphthol:

99

Production. The following abridged specifications are intended to illustrate processes for the

manufacture of symmetrical and asymmetrical disazo direct dyes.

C. I. Direct Yellow 12,

24895, (**97**) [*2870-32-8*]: 590 kg of 4,4′-diaminostilbene-2,2′-disulfonic acid are adjusted with water and ice to a volume of approximately 5500 L and a temperature of 5 °C and bisdiazotized with 220 kg sodium nitrite as 23 % solution; volume 6000 – 7000 L, temperature 20 – 22 °C.

Next, 312 kg of phenol are dissolved with 1500 L of water and 150 L of 30 % sodium hydroxide solution and 225 kg of soda are added. To this is transferred the above bisdiazotized solution. Then, 160 L of 30 % sodium hydroxide solution is added over 1 h. On the following morning, the solution is heated to 70 °C, and after addition of 240 L of 30 % hydrochloric acid, the dye is salted out with 12 % rock salt, calculated on the volume. Yield: 2090 kg.

Approx. 5500 kg of the damp press cake, corresponding to 2940 kg of 100 % product, 3500 kg of 94 % ethanol, 520 kg of soda, 870 L of 30 % sodium hydroxide solution, and 840 kg of ethyl chloride are kept in a closed stirrer vessel for 24 h at 100 °C (5 – 5.5 bar). The mixture is then cooled to 70 °C and transferred at its own pressure to a distilling vessel, from which the ethanol is distilled with direct steam via a column. After being cooled to 80 °C, the mixture is suction filtered and dried at 100 °C.

C. I. Direct Blue 15, 24400 (**92**) [*2429-74-5*]. 105 kg of dianisidine dihydrochloride is charged into 6000 L of water and 400 L of 31 % hydrochloric acid. Then 2000 kg of ice is added and the solution is bisdiazotized at 0 °C with 200 kg of sodium nitrite and stirred for 4 h.

To 210 kg of H acid as neutral solution 4000 L of a 20 % sodium carbonate solution is added and then 3000 kg of ice to cool to 0 °C. This solution is run in the bisdiazonium salt solution and stirred overnight.

Then the solution is heated to 80 °C, 4600 kg of sodium chloride is added, and the dye is filtered and dried in vacuo at 95 – 100 °C. Yield: 7600 kg.

Types $D_1 \rightarrow K \leftarrow D_1$ and $D_1 \rightarrow K \leftarrow D_2$

The most important coupling component for these types is the compound **100**, which is produced by phosgene treatment of the I acid.

100

101

Dyes with a urea bridge, –HN–CO–NH–, are also obtained by phosgene treatment of aminoazo compounds (see Section 4.1.6). The so-called I acid imide (**101**), resorcinol and *m*-phenylenediamine are also of importance. Examples of dyes are: *C. I. Direct Orange 26,* 29150 (**102**) [*3626-36-6*],

102

C. I. Direct Red 250, 29168 (**103**),

103

and *C. I. Direct Red 23,* 29160 (**104**) [*3441-14-3*].

104

The dye **104** is obtained by simultaneous coupling of one equivalent each of diazotized aniline and 4-aminoacetanilide to I acid urea (**100**). Although it only possesses average fastness properties, it enjoys great importance and because of its good leveling power is used for dyeing union fabrics, polyamide, and chrome leather.

By coupling diazotized dehydrothio-*p*-toluidinesulfonic acid to resorcinol and subsequent coupling of diazotized aniline to the monoazo dye formed one obtains *C. I. Direct Orange 18,* 20215 (**105**) [*5915-59-3*]. The product likewise represents an important substantive dye.

105

4.1.2.2. Secondary Disazo Dyes

Type D → M → K. For the manufacture of secondary disazo dyes, a diazotized amine D is coupled to an amine M with free *para* position, which in turn is diazotized and coupled to a coupling component K (series coupling).

Dyes of this type mostly have a straight-chain structure and often contain groups that increase substantivity, such as I acid, I acid derivatives, in particular with acylated amino groups, urea bridges, or benzoylamino groups. The shades in this range extend from orange through red, violet, and blue to black.

Examples: From 4-aminoazobenzene-4′-sulfonic acid and benzoyl I acid *C. I. Direct Red 81,* 28160 (**106**) [*2610-11-9*], is obtained. This dye represents an important red grade.

106

C. I. Direct Black 51, 27720 (**107**) [*3442-21-5*], is produced by coupling a mixture of diazotized 3- and 5-aminosalicylic acid to 1-naphthylamine and subsequent alkaline coupling to γ acid.

107

4.1.3. Trisazo Dyes

The trisazo dyes include in particular blue, green, and black grades. Benzidine, which here, too, used to be an important bisdiazo component, has been replaced by other diamines, such as *o*-tolidine, 4,4′-diaminobenzanilide (DABA), or 4,4′-diaminodiphenylamine-2-sulfonic acid (DADPS).

The most important synthesis principle in this range is the type $K_1 \leftarrow D_1 \rightarrow K_2 \leftarrow D_2$. The sequence of the three couplings depends on the nature of the components.

An example is *C. I. Direct Green 85,* 30387 (**108**).

108

phenol $\xleftarrow{3}$ *o*-tolidine $\xrightarrow[a]{1}$ H acid $\xleftarrow[alk]{2}$ aniline

The reaction commences with stepwise coupling of the *o*-tolidine and then aniline with H acid, followed by coupling of this aminodisazo intermediate with phenol.

With *C. I. Direct Black 166,* 30026 (**109**), the first step is the acid coupling of 3,3′-diaminobenzanilide to H acid, followed by alkaline coupling of aniline to the monoazo dye and finally coupling of the disazo dye to *m*-phenylenediamine.

109

m-phenylenediamine $\xleftarrow{3}$ DABA $\xrightarrow[a]{1}$ H acid $\xleftarrow[alk]{2}$ aniline

C. I. Direct Black 150, 32010 (**110**) [*6897-38-7*], is produced by double (alkaline) coupling of bisdiazotized 4,4′-diaminodiphenylamine-2-sulfonic acid to γ acid and subsequent single coupling to *m*-phenylenediamine.

110

γ acid $\xleftarrow[alk]{1}$ DADPS $\xrightarrow[alk]{1}$ γ acid $\xrightarrow{2}$ *m*-phenylenediamine

Among the trisazo dyes, the synthesis principle of series coupling of the type $D \rightarrow M_1$

$\rightarrow M_2 \rightarrow K$ is also of importance. This group contains a number of dyes with good to very good general fastness properties.

Anilinesulfonic acids are chiefly used as starting component D, naphthylamine and Cleve acids as middle components M_1 and M_2, and I acid, its *N*-phenyl derivatives, H acid, γ acid, and their derivatives as final component K. This type mainly possesses blue and green shades. Example: *C. I. Direct Blue 78,* 34200 (**111**) [*2503-73-3*].

111

2-aminobenzene-1,4-disulfonic acid $\rightarrow$ Cleve acid-7 $\rightarrow$ 1-naphthylamine $\rightarrow$ *N*-phenyl I acid

In the manufacture of trisazo dyes, good yield and purity during final coupling are often obtained only in the presence of pyridine or other bases as coupling accelerators [35]. Intermediate isolation and separation of impurities prior to continuation of coupling are also frequently necessary.

The use of pyridine during final coupling (pyridine coupling) is illustrated in the following abridged manufacturing specification for *C. I. Direct Green 33,* 34270:

2-aminonaphthalene-8-sulfonic acid $\rightarrow$ 3,5-xylidine $\rightarrow$ 2-ethoxy Cleve acid-6 $\rightarrow$ *N*-acetyl H acid

Final Diazotization: The disazo dye produced by the usual method aminocroceic acid $\rightarrow$ sym. *m*-xylidene $\rightarrow$ 2-ethoxy-Cleve acid-6 (batch size: 81 kg aminocroceic acid 100 %) is stirred in the form of a press cake in 600 L of water with 500 L of 50 % acetic acid. Then 26.5 kg of sodium nitrite in the form of a 30 % solution is added at 25 °C. After stirring overnight, a reddish-brown solution is obtained. *Final coupling:* To 104 kg of H acid 100 %, dissolved in 500 L of water, are added 32 L of 40 % sodium hydroxide solution and 17 kg of soda; the mixture is heated to 70 °C and 50 kg of acetic acid anhydride is added. After acetylation is completed, the mixture is transferred to 1500 L of pure pyridine and 2000 kg of ice. The diazotizing solution is added at 0 – 12 °C over the course of 1/2 h. After a further hour, 375 kg of sodium hydrogen carbonate is added and after 1 h has expired, the mixture is heated to 60 °C by indirect steam. Following the addition of 8 % rock salt, the temperature is maintained at 60 °C for a further hour, and the dye is filtered and dried at 110 °C (drum drier or circulating air cabinet). Then yield is approx. 360 kg.

Other possible combinations are only of minor importance compared with the trisazo dyes manufactured according to the synthesis principles mentioned.

4.1.4. Tetrakisazo Dyes

Numerous syntheses are possible for these dyes, which all yield only dark shades. Here, too, only a few types are of industrial importance.

A further extension to the trisazo dyes on the principle of series coupling $D \rightarrow M_1 \rightarrow M_2 \rightarrow M_3 \rightarrow K$ offers no advantages, because the intermediate isolation that is frequently necessary leads to yield losses and a chain extension is therefore ruled out on economic grounds. This is also reflected in the number of polyazo dyes given in the Colour Index [7, vol. 4, p. 4325]. Although 78 tetrakisazo dyes with eleven different synthesis principles are listed, only 14 dyes with five and more azo groups are mentioned, two of which are specified with eight azo groups (see top of next page).

An example of type $D \rightarrow M_1 \rightarrow M_2 \rightarrow M_3 \rightarrow K$ is C. I. Direct Dye, 35850 [*8002-98-0*] (brown).

sulfanilic acid $\rightarrow$ *m*-toluidine $\rightarrow$ Cleve acid-6 $\rightarrow$ *m*-toluidine $\rightarrow$ 1-nitrophenylene-2,4-diamine

A number of important direct dyes are derived from type $K_1 \leftarrow M_1 \leftarrow D \rightarrow M_1 \rightarrow K_1$: C. I. Direct Black 22, 35435, (**112**) [*6473-13-8*] is produced via the primary disazo dye from 4,4′-diaminodiphenylamine-2-sulfonic acid and two equivalents of γ acid. This dye is bisdiazotized and coupled to two equivalents of *m*-phenylenediamine.

112

113

114

Pattern:

Another example is *C. I. Direct Black 151,* 35436 (**113**)

Here, too, the disazo dye is initially prepared from bisdiazotized 4,4′-diaminodiphenylamine-2-sulfonic acid with 2 equivalents of γ acid. Coupling is then again carried out stepwise to γ acid and finally to *m*-phenylenediamine.

C. I. Direct Black 19, 35255 (**114**) [*6428-31-5*], is also an important dye. It is obtained by coupling two equivalents of *p*-nitraniline to H acid, sulfhydrate reduction of the two nitro groups, and coupling of the bis-diazotized intermediate compound with two equivalents of *m*-phenylenediamine (see top of page 45).

4.1.5. Condensation Dyes

These dyes are produced by condensation of nitro compounds (see also Section 2.2.1).

Alkaline condensation of dinitrostilbenedisulfonic acid with aminoazo compounds produces a number of highly fast substantive dyes with industrial importance, especially in the shades orange, scarlet, and brown [36]. Example: *C. I. Direct Orange 39,* 40215 [*1325-54-8*], is obtained by condensation of 4-aminoazobenzene-4′-sulfonic acid with dinitrostilbenedisulfonic acid in aqueous sodium hydroxide solution. The main product formed is the tetrakisazo dye of the stilbene-2,2′-disulfonic acid (**115**), as well as the corresponding azoxy compounds. No uniform product is obtained, since part of the aminoazo compound is consumed as reducing agent. Condensation dyes are often purified by aftertreatment with reducing agents or such as glucose or sodium sulfide. Abridged specification: 468 kg of 100 % 4,4′-dinitrostilbene-2,2′-disulfonic acid as sodium salt is stirred with 1000 L of water and adjusted to a weakly alkaline pH value with sodium hydroxide solution. Then 440 L of 30 % sodium hydroxide solution is added and 346 kg of 100 % 4-aminazobenzene-4′-sulfonic acid introduced as sodium salt. After the contents of the tank have been diluted to 4500 L, the temperature is raised and maintained for 14 h at 100 °C. The condensation product is transferred into 10000 L of water and 39 kg of sodium sulfide is then added. The temperature is raised to 85 °C and maintained there for 1/2 h; then salting-out carried out with 12 % rock salt, calculated on the total volume. Isolation is carried out at 70 °C using a filter press. The dye is given a final washing

115

with 9000 L of a 10 % rock salt solution heated to 50 °C. The yield is approx. 780 kg dry.

Table 10 shows further examples of condensation dyes obtained from the corresponding aminoazo compounds and 4,4′-dinitrostilbene-2,2′-disulfonic acid.

4.1.6. Direct Dyes with a Urea Bridge

By the end of the 19th century, BASF had discovered that the reaction of aminoazo dyes with phosgene in an aqueous solution in the presence of soda resulted in valuable symmetrical urea azo dyes [37]:

A = azo dye radicals

The urea bridge can also be introduced into direct dyes with 4,4′-diaminodiphenylurea derivatives by means of bisdiazotization and coupling (see (**98**) in page 40). *C. I. Direct Yellow 50,* 29025 (**116**) [*3214-47-9*]

116

is obtained, for example, by phosgene treatment of two equivalents of aminoazo dye prepared from diazotized 2-aminonaphthalene-4,8-disulfonic acid coupled to *m*-toluidine.

Other examples of symmetrical direct dyes with a urea bridge are shown in Table 11.

Aminodisazo and aminotrisazo dyes can also be treated with phosgene, largely red and brown shades being obtained.

Example: *C. I. Direct Red 80,* 35780 [*2610-10-8*], is rendered accessible by phosgene treatment of the aminodisazo dye **117**:

117

By mixing two different aminoazo compounds A–NH_2 and B–NH_2 and subsequent phosgene treatment, the asymmetrical diphenylurea direct dye **118** is obtained in addition to the two symmetrical members.

118

There are a number of yellow substantive dyes synthesized by this principle. Example: *C. I. Direct Yellow 41,* 29005 (**119**) [*8005-53-6*], is obtained by phosgene treatment of an equimolar mixture of bases A (sulfanilic acid → cresidine) and B (*p*-nitroaniline → salicylic acid and reduction of the NO_2 group). The mixture additionally contains the two corresponding symmetrical dyes.

119

4.1.7. Triazinyl Dyes

The principle of linking two or three azo dyes by means of a triazine ring was established by Ciba patents [38]. The triazine bridge increases the substantivity of the dyes, in a similar manner to the −NH−CO−NH− group. Production is based on cyanuric chloride, the three chlorine atoms of which can be replaced in stages by nucleophilic radicals under different conditions (see Section 2.3.2).

The procedure that can be adopted is for intermediate products with amino groups (e.g., H

Table 10. Examples of condensation dyes made from aminoazo compounds and 4,4′-dinitrostilbene-2,2′-disulfonic acid

Aminoazo compound	Condensation dye	Aftertreatment with
	C.I. Direct Orange 40, 40265 [*1325-62-8*]	Na_2S
	C.I. Direct Red 76, 40270 [*1325-63-9*]	glucose
	C.I. Direct Brown 78, 40290 [*1325-65-1*]	–

Table 11. Aminoazo compounds for symmetrical direct dyes with a urea bridge

Aminoazo dye	Direct dye
	C.I. Direct Yellow 26, 25300 [*2829-42-7*]
	C.I. Direct Yellow 33, 29020 [*6420-28-6*]
	C.I. Direct Red 79, 29065 [*1937-34-4*]

acid) to be condensed with cyanuric chloride and the reaction product subsequently attached to the diazo component, or aminoazo dyes are reacted directly with cyanuric chloride. In the relevant commercial azo dyes, the third chlorine atom in the cyanuric chloride is usually reacted with aniline or ammonia and less frequently left unchanged.

Of interest, here, are dyes that yield green shades through combination of a blue and yellow component.

Example: *C. I. Direct Green 26,* 34045 (**120**) [*6388-26-7*].

120

The blue component (H acid → cresidine → H acid) is linked with the triazine ring by means of the amino group of the H acid; after reduction of the nitro group, the yellow component (*p*-nitroaniline → salicylic acid) replaces the second chlorine atom of cyanuric chloride and aniline the third chlorine atom. The dye consti-

tutes a very pure, clear, bluish green with very good fastness properties.

4.1.8. Copper Complexes of Substantive Azo Dyes

Under certain structural conditions, azo dyes are capable of forming metal complexes (see Section 2.3.4). A process for the complexing of *o,o′*-dihydroxyazo dyes with copper by reaction of these dyes with copper sulfate in a weakly acid solution was described for the first time in 1915 [39].

The introduction of copper into conventional substantive dyes often increases their light and wetfastness considerably, since complexing blocks the hydrophilic groups. Copper complexes of *o,o′*-disubstituted azo dyes are chiefly of interest for direct dyes. Substituents especially capable of complexing are hydroxyl, methoxy, carboxy, and carbomethoxy groups. BASF developed the oxidative copper treatment process in which on the basis of *o*-hydroxyazo dyes, copper complexes of the corresponding *o,o′*-dihydroxyazo dyes are obtained [40].

The possibility of first converting suitable azo compounds into copper complexes, and subsequently using them as coupling components for the synthesis of azo direct dyes, was also described.

As in the case of the metal-free direct dyes, a large diversity of structures is encountered; here, too, there are direct dyes with pyrazolones, substituted 4,4′-diphenylamines, or the 1,3,5-triazine ring, urea and stilbene derivatives, and condensation dyes.

For each dye it is necessary to establish the most favorable conditions under which copper-containing products with improved properties are obtained. Because none of the known complexing processes provides optimum results in all instances, the production of certain dyes or complexing variations is protected by a large number of patents.

Especially for ecological reasons, however, the importance of copper complex dyes is decreasing. This applies in particular to the copper aftertreatment.

A demethylating copper treatment of dyes synthesized with *o*-dianisidine results in light-fast blue grades, such as *C. I. Direct Blue 98,* 23155 [*6656-03-7*], a copper complex of **121**;

121

and *C. I. Direct Blue 84,* 23610 [*13569-92-1*], a copper complex of **122**.

122

The following additional examples of substantive copper complex dyes can be mentioned: *C. I. Direct Violet 47,* 25410 [*13011-70-6*], a copper complex of **123**;

123

and *C. I. Direct Green 23,* 31985, a copper complex of **124**.

124

4.2. Direct Dyes with Aftertreatment

For supplementary literature see [41] and [42, vol. 2, p. 46]

In spite of the reactive dyes with their outstanding wetfastness, the direct dyes continue to hold a large share of the market for inexpensive cellulose and paper dyes. Apart from the new developments to replace the old established benzidine dyes, considerable efforts are being made to improve the fastness properties of direct dyes by aftertreatment. The various aftertreatment methods are described below in the order of their present importance.

4.2.1. Aftertreatment with Cationic Auxiliaries

Aftertreatment of substantive dyeings with organic, cationic substances has lately begun to gain increasingly in importance. Improvements are obtained in particular in wetfastness properties, especially fastness to water, washing, and wet pressing, as well as fastness to perspiration and cross-dyeing.

The cationic compounds precipitate the (anionic) dyes from their aqueous solutions and on the fiber form higher molecular mass, scarcely soluble, saltlike compounds with the dyes. Removal of the latter from the fiber is thus made more difficult. A number of companies have compiled their own ranges of this type of aftertreatment agent.

Cationic textile auxiliaries can be divided into two groups: quaternary ammonium compounds and cationic formaldehyde condensation resins.

Quaternary Ammonium Compounds. These contain aliphatic and/or cycloaliphatic radicals (R^1 to R^4 in Eq. 12), of which at least one represents a long-chain alkyl radical (with more than five C atoms). The compounds react with the dyes in accordance with the following pattern:

(12)

(F) = dye radical

Use is made, for example, of cetyldimethylbenzylammonium chloride and pyridinium compounds of the type

X^- R = long-chain alkyl radical
X = Cl, SO_4H, etc.

In addition, the quaternary ammonium compounds mostly possess strong affinity for the cellulosic fiber, whereby the insoluble reaction product is anchored even more firmly with the dye on the fiber. This high affinity can, however, also result in nonuniform improvements in fastness properties. This behavior also prevents the use of circulating liquor dyeing machines, because even with addition of aftertreatment agent in portions (e.g., in the case of wound packages) no completely uniform aftertreatment can be guaranteed.

The action of quaternary ammonium compounds on the dyed fiber in many cases produces a change of shade.

A further disadvantage is the possible elimination of aliphatic amines, e.g., in an alkaline medium in the presence of anionic substances or at excessive drying temperatures. This can cause an unpleasant (fishy) odor to arise. In such cases, an acid aftertreatment is necessary.

Cationic Formaldehyde Condensation Resins. An appreciable improvement in wetfastness properties is obtained by aftertreating the dyeings with polymeric condensation resins containing strongly basic groups. This leads to the formation of insoluble salts from resin cation and dye anion.

The most important resins of this type are obtained from dicyanodiamide (**125**) by condensation with formaldehyde and hydrochloric acid:

125

Suitable blending of ammonium salts of fairly strongly basic amines (e.g., melamine or guanidine) and acid condensation with formaldehyde enables favorable conditions to be obtained with regard to solubility and cross-linking of the cationic condensation resins.

The water-soluble resins are inexpensive, and compared with quaternary ammonium compounds relatively small quantities often suffice to achieve a marked improvement in wet fastness and fastness to perspiration. A disadvantage is a certain influence on light fastness. This may be lowered by one to two steps on the eight-step blue scale, when these resins are used on materials dyed by substantive dyes. Formaldehyde condensation resins are therefore used especially for articles in which wet fastness and fastness to perspiration are important, but light fastness is less crucial, e.g., lining fabrics.

4.2.2. Aftertreatment with Formaldehyde

The wetfastness properties of substantive azo dyes containing free amino or hydroxyl groups as terminal groups (final component of coupling, e.g., resorcinol or *m*-phenylenediamine) can be improved by aftertreating the dyed fiber material with aqueous formaldehyde solution. The conditions for the presence of free amino groups can also be satisfied by subsequent reduction of nitro groups or hydrolysis of acylamino groups. During reaction with formaldehyde, methylene bridges are formed between two dye molecules; i.e., an enlargement of the molecule occurs and hence an improvement in wetfastness, whereas light fastness is not influenced.

Because of a lack of storage stability in dyeings treated by this method, the formaldehyde aftertreatment is mainly confined to dark shades (brown and black).

The first patent on this aftertreatment method was granted to Geigy as early as 1899 [43]. Although the basic, simple process has remained virtually unchanged, its importance has lately declined sharply for ecological reasons.

4.2.3. Diazotization Dyes

Direct dyes containing one or more diazotizable amino groups in the dye molecule permit further diazotization on the fiber and subsequent coupling with a "developer." β-Naphthol can be used as a developer for orange, red, brown, blue, and black shades, 1,3-phenylenediamine and 2,4-diaminotoluene for brown, gray, and black shades.

The shade of the dye applied to the material usually changes considerably as a result of this aftertreatment. wetfastness and fastness to perspiration are greatly improved, light fastness remains unchanged. The amino group needed for diazotization is introduced by final coupling with an amine, an aminonaphtholsulfonic acid, or an amino-acylaminonaphtholsulfonic acid or by reduction of a nitro or hydrolysis of an acylamino group. "Development" results in enlargement of the dye molecule without further solubilizing groups being added.

The time-consuming process necessitates careful handling. Exposure to sunlight or partial drying of the diazotized dyeing should thus be avoided.

Diazotization dyes now enjoy only minor importance.

Example: *C. I. Direct Red 145,* 17805 (**126**) [*6771-94-4*], yields a clear yellowish red when developed with β-naphthol.

126

4.2.4. Aftertreatment with Metal Salts

This method is dealt with briefly, mainly on historical grounds, because for reasons connected with wastewater pollution and because of certain performance drawbacks it is hardly used any longer.

Metal complexing (see Section 4.1.8) cannot be carried out until after the fiber has been dyed. This aftertreatment, mainly with copper salts (sulfate, acetate), takes place under mild conditions, so that, for example, no metal complexing with an *o*-methoxyazo group occurs. Suitable complexing systems, on the other hand, are *o,o′*-dihydroxy-, *o*-hydroxy-*o′*-carboxy-, *o*-hydroxy-*o′*-carbomethoxy-, and *o*-carboxy-*o′*-aminoazo groups.

4,4′-Diaminodiphenyl-3,3′-dicarboxylic acid (**127**), 4,4′-diaminodiphenyl-3,3′-bisoxyacetic acid (**128**), and 4,4′-diaminodiphenylurea-3,3′-dicarboxylic acid (**129**) have proved successful as diamino components for the synthesis of disazo copper-aftertreated dyes.

127

128

129

130

Metal complexing results in blocking of solubilizing groups; aggregation increases, the dye becomes less soluble, and an improvement in wet fastness occurs. Although the light fastness is generally also improved by this aftertreatment, fastness of the dyeings to perspiration is frequently reduced. The shades generally become duller and flatter. Catalytic action of traces of heavy-metal ions that are present can cause fiber tendering to occur in the presence of detergents containing oxidizing agents (peroxides).

An example of a direct dye suitable for copper aftertreatment is *C. I. Direct Blue 167,* 24560 (**130**), see top of the page.

5. Cationic Azo Dyes

Cationic azo dyes carry a positive charge in the colored portion of the molecule. The salt-forming counterion is, in most cases, the colorless anion of a low molecular mass inorganic or organic acid. The positive charge is generally carried by nitrogen, but there are also dyes in which this function is taken on by sulfur or phosphorus (see Section 5.5).

The positive charge may be either localized at an ammonium group (see, e.g., **131**)

131

or delocalized across the dye cation. The transition between the two dye classes is continuous. At one extreme, this leads to the dark blue compound **132**, which is no longer considered an azo dye but classified as a diazacyanine dye (→ Methine Dyes and Pigments).

132 At an intermediate position, compound **133** has its positive charge much less delocalized because of the high energy of the quinoid resonance extreme **133b**.

Finally, in compound **134** the structure does not permit a charge delocalization from the benzimidazolium ion to the back ring azo dye substituent.

134

Both **133** and **134** confer a similar orange-red color to polyacrylonitrile and are classified as cationic azo dyes.

History. Basic dyes of the azo class are among the earliest known synthetic dyes. They were used originally for dyeing cotton mordanted with tannin and potassium antimonyl tar-

trate and wool from neutral solution. They continue to occupy a place of minor importance for dyeing leather, paper, plastics, and waxes, and as constituents of graphic arts colors.

The preparation of the first cationic azo dye, Vesuvin, was described by C. Martius in 1863. It is obtained by coupling diazotized *m*-phenylenediamine to an excess of the same amine. An analogous dye from toluylenediamine was reported by P. Gries in 1878. Chrysoidines, coupling products of aniline or toluidines to *m*-phenylenediamine or toluylenediamine, were reported by H. Caro in 1875 and O. N. Witt in 1876. These were followed in 1886 by cationic safranine azo dyes, obtained by coupling diazotized diethylphenosafranine to phenols or aromatic amines (→ Azine Dyes), and by dyes produced by coupling diazotized aminophenyltrimethylammonium chloride to phenols and aromatic amines. Both groups formed the basis of the Janus dye product line, which gained great importance for a time in dyeing weighted silk.

When polyacrylonitrile fibers appeared on the market, an intense research effort in the area of cationic azo dyes was stimulated worldwide at all the leading dye plants. These materials now occupy a place of importance in all significant product lines.

Azo dyes with several cationic charges, which are substantive dyes for cellulose, are increasingly being used for coloring bleached sulfite cellulose.

The cationic charge may be introduced into the dye molecule via either the diazo component or the coupling component.

5.1. Cationic Charge at the Coupling Component

Amino groups, amidine residues, trialkylammonium, or cyclic ammonium groups may serve as carriers of the cationic charge in the coupling components.

5.1.1. Polyamines as Coupling Components

Chrysoidines are obtained by coupling diazonium salts of aniline, toluidines, or mixtures thereof to 1,3-phenylenediamine, 2,4- or 2,6-toluylenediamine, or mixtures of these diamines. These dyes confer muted yellow to orange shades to paper, leather, and polyacrylonitrile fibers. When they are mixed with malachite green and fuchsin, medium-fast black shades are obtained on polyacrylonitriles. A mixture of chrysoidine with Crystal Violet or Victoria Pure Blue is used to adjust the color of nigrosine hectograph inks [44].

Examples are *C. I. Basic Orange 1,* 11320 (**135**) [*4438-16-8*] the azo dye from diazotized aniline and 2,4-diaminotoluene,

135

and *C. I. Basic Orange 2,* 11270 (**136**) [*532-82-1*] the dye from aniline and *m*-phenylenediamine.

136

The dye *Astrachrysoidine RR* is a mixture of several compounds.

A mixture of 13 g aniline, 12.5 g *o*-toluidine, and 3.0 g *p*-toluidine is diazotized in aqueous hydrochloric acid solution at 0 °C using 66.5 mL of a 30 g/100 mL sodium nitrite solution. Excess nitrite is destroyed prior to coupling using sulfamic acid. The diazotized solution is added in a thin stream and at 0 °C to a solution of 16.5 g of *m*-phenylenediamine and 18.5 g of 2,4-diaminotoluene in 1000 mL of water. The coupling solution is then adjusted to pH 3 – 3.5 by addition of dilute aqueous sodium acetate. After completed coupling, the pH of the reaction mixture is adjusted with hydrochloric acid using congo red indicator. The precipitated dye is collected by filtration and dried to yield 75 g of a dark orange powder.

Chrysoidine dye salts of dodecylbenzenesulfonic acid are soluble in glycols and glycol ethers and are used in the production of inks, printing inks, and varnishes [45].

Mono- and disazodyes from diazotized anilines and 2,4,6-triaminotoluene dye wool and cotton [46].

Vesuvin and *Bismarck Brown* products are obtained when *m*-phenylenediamine, 2,4- and 2,6-diaminotoluene, or mixtures thereof are treated with nitrite in acidic solution, or when a mixture of the amines and nitrite is acidified. The final products consist of mixtures of monoazo, disazo, and polyazo dyes, with the disazo species probably predominating in commercial products. In the presence of sodium chloride, the dye is salted out immediately after its formation and thereby the formation of polyazo dyes is prevented.

Astravesuvin R (**137**), *C. I. Basic Brown 4*, 21010, serves as an example:

137

A mixture of 2,4- and 2,6-diaminotoluene (28.5 g, molar ratio 2 : 3) and 25 g of *m*-phenylenediamine is dissolved in 1200 mL water at room temperature and mixed with 67 mL of 30 g/100 mL aqueous sodium nitrite. After addition of 450 g of sodium chloride and 800 g of ice, which results in a temperature of − 10 to − 12 °C, 86 mL of concentrated hydrochloric acid is added rapidly. Finally, the pH is adjusted to 3 – 3.5 by the addition of dilute sodium acetate solution. After several hours, the coupling solution is adjusted to pH 1 and the precipitated dye is collected by vacuum filtration and dried to yield 90 g of a yellow-brown powder.

Liquid Vesuvin dye solutions may be obtained by diazotization and coupling of aromatic diamines [47–49] or, if desired, also in mixture with aromatic monoamines [50] in carboxylic acid solutions. The dye mixtures can be alkylated with alkylene oxides [51].

m-Phenylenediamine (105 g) is added to a mixture of 360 g glacial acetic acid, 80 g water, and 60 g ethylene glycol followed by stirring and warming to dissolve. The temperature is lowered to 8 – 10 °C and, at this temperature, 47 g sodium nitrite is added in portions over a period of 1.5 h. After addition is completed, the mixture is stirred for 1/2 h, 10 g *m*-phenylenediamine is added, and stirring is continued for another 3 h at 8 – 13 °C. Finally, the reaction is warmed to 35 – 40 °C for 1 h followed by chilling of the dye solution.

Vesuvines are used chiefly for dyeing paper containing wood pulp.

5.1.2. Heterocycles as Coupling Components

If heterocyclic polyamines, e.g., 2,4-diamino-6-hydroxypyrimidine, are used as coupling components with aromatic diazonium compounds, dyes are obtained that color polyacrylonitrile in lightfast yellow shades and that are characterized by excellent leveling properties [52]. An example is **138** [*6979-64-2*].

138

Coupling Components with Amidine Moieties. Well-leveling azo dyes are also obtained when pyrazolones substituted in the 1-position by an amidine residue are used as coupling components. The diazo components are predominantly substituted by methyl and methoxy groups [53]. An example is **139** [*68936-08-3*].

139

By reaction of these dyes with formaldehyde and acetone, condensation products suitable for wetfast dyeing of cotton are obtained [54].

5.1.3. Coupling Components with Alkylammonium Groups

Numerous cationic azo dyes contain a dialkylaminoalkyl or a trialkylammonium group as the charge carrier in the coupling component.

5.1.3.1. Coupling Components with Dialkylaminoalkyl Groups

Dyes bearing one or more dialkylaminoalkyl substituents have found favor for coloring paper because they behave as substantive dyes which, when properly substituted, result in a practically colorless waste liquor. A suitable starting material for the preparation of such dyes is the reaction product of 2 mol dialkylaminopropylamine with 1 mol cyanuric chloride. This may be converted to an acetoacetarylide, which,

140

when coupled with diazotized 2-(4′-aminophenyl)-5-methylbenzothiazole, yields the yellow dye **140** [*91458-38-7*] with greenish cast suitable for coloring paper [55].

By reaction of a similar triazine component with J acid (1-hydroxy-6-aminonaphthalene-3-sulfonic acid), followed by coupling with diazotized 4-aminoazobenzene, the cationic substantive azo dye **141** [*71032-95-6*] is obtained, which colors paper in red hues.

141

Copper complexes of these materials or of the analogous γ acid (1-hydroxy-7-aminonaphthalene-3-sulfonic acid) dyes confer gray-violet [56] or blue hues [57], [58] to paper, respectively, or dye particles of glass in navy blue tones [59]. A *commercial product* of this series is Cartasol Red K-2B (Clariant).

These kinds of triazine moieties may also be part of pyrazolone and pyridone coupling components [60], [61].

The dialkylaminoalkyl residue may also be connected directly to the phenyl residue of the acetoacetanilide. By coupling with diazotized 2-(4-aminophenyl)benzimidazole, a yellow dye suitable for paper is formed [62].

The dialkylaminoalkyl group may be connected to the N-1 atom of 3-methylpyrazolone [63], to the amide nitrogen atom of *N*-phenylpyrazolone-3-carbonamide [64], to the N-2 atom of 3-cyano-2,4,6-trisaminopyridine [65], or to the amino group of 2-amino-4,6-dihydroxypyridine [66].

3- or 6-hydroxy-2-naphthoic acid amides bearing dialkylaminoalkyl residues on the nitrogen atom lead to orange dyes for polyacrylonitrile or paper when coupled with diazotized aniline [67], [68], or to red dyes, soluble in glycol ethers and useful for ink-jet printing, when coupled with diazotized 3-amino-4-methoxybenzenesulfonic acid-*N,N*-diethylamide [69], or to substantive red dyes when the diazo component is a 2-(4′-aminophenyl)benzotriazole [70]. Dialkylaminoalkyl amides of J acid have been used to prepare red dyes for polymeric materials, especially paper, with 4-acetylaminoaniline as diazo component [71], [72].

5.1.3.2. Aromatically Linked Trialkylammonium Groups

Exhaustive alkylation of aminonaphthols, such as 2-amino-7-naphthol, and coupling with diazotized aromatic amines generates yellow, orange, red, and brown cationic azo dyes [73], [74]. Compound **142** dyes human hair and polyacrylonitrile in brown shades [75].

142

Exhaustively alkylated 4-aminodiphenylamine is also suitable as a coupling component. Dyes (e.g., **143**) [*41025-69-8*] obtained by reaction with diazotized nitroanilines confer fast yellow, orange, and red shades to polyacrylonitrile [76].

143

By exhaustive alkylation of 3-aminophenylpyrazolone compounds, a trimethylammonium moiety may be introduced into this coupling component. The disazo dye **144** [*86565-98-2*] colors paper in orange shades [78] (see bottom of page).

The trialkylammoniumphenyl group may also be part of acetoacetic acid arylides [77] or be connected to the coupling component via an ether link (see **145**) [*84041-74-7*] [79].

145

144

5.1.3.3. Trialkylammoniumalkyl-Substituted Anilines

Dialkylanilines that carry a cationic substituent at one of the alkyl groups are among the most important coupling components of cationic azo dyes.

By reaction of *N*-ethyl-*N*-(2-chloroethyl)aniline or of *N*-ethyl-*N*-(2-chloroethyl)-*m*-toluidine with trimethylamine, ammonium salts are obtained that, upon coupling with diazotized aromatic amines, yield a large number of valuable dyes for coloring polyacrylonitrile.

C. I. Basic Red 18, 11 085 (**146**) [*25198-22-5*] is derived from the diazo component 2-chloro-4-nitroaniline [80].

146

It is a component of all major product lines used for dyeing polyacrylonitrile.

Commercial products are Astrazon Red GTL (DyStar), Diacryl Red GTL-N (Mitsubishi), Sumiacryl Red F-GTL (Sumitomo), and Taiacryl Red GTL (T&T Ind.).

The corresponding dye from 2,6-dichloro-4-nitroaniline as the diazo component is also of commercial importance.

Other suitable diazo components are 4-nitroaniline (orange), 2,6-dichloro-4-nitroaniline (yellow-brown) [81], 2-cyano-4-nitroaniline (red) [82], 2,6-dichloro-4-(*N,N*-dimethylsulfamoyl)aniline (orange), 4-aminobenzophenone (yellow), 2,4,6-trichloroaniline (yellow), 2,4,6-tribromoaniline

(yellow), 2,6-dibromo-4-nitroaniline (yellow brown) [83], and 2-cyano-5-chloroaniline (orange).

Heterocyclic diazo components include 2-aminothiazole substituted with ester groups [84], and the coupling product of diazotized 4-nitroaniline with 2-amino-3-cyanothiophene [85]. An especially favored starting material is 3-phenyl-5-amino-1,2,4-thiadiazole, which is also used in the production of disperse dyes. It yields very bright dyes for coloring polyacrylonitrile [80]. An example is **147** [*85283-77-8*].

147

A commercial product is Astrazon Red BBL (DyStar).

By coupling aminobenzothiazoles to the quaternary ammonium bases red cationic dyes (e.g., **148**) are obtained [86].

148

This is to be contrasted with the blue diazacyanines, which derive from the quaternized benzothiazole residue.

Dye affinity to polyacrylonitrile and, thereby, the dyeing rate may be enhanced by introducing an aralkyl residue [87] or an aryloxyalkyl residue [88] in place of an alkyl group at the trialkylammonium group.

The solubility of these dyes is significantly enhanced by introduction of alkenyl [89], hydroxypropyl [90], or polyetheralkyl [91] moieties into the trialkylammonium group. The trialkylammonium group may also be a component of a heterocyclic ring [92]. When the trialkylammonium residue contains an alkyl chain of more than 11 carbon atoms, the dyes become soluble in aliphatic and alicyclic hydrocarbons and can be used for the production of printing inks [93]. Also *C. I. Basic Black 8* is recommended as a dye for ink-jet printing [94]. The quaternization to the trialkylammonium residue may also be carried out using dialkyl phosphites or phosphonates [95].

With aromatic diamines as the diazo components, such as 4,4′-diaminodiphenylsulfone, basic disazo dyes are obtained which are suitable for dyeing acid-modified polyamide materials [96].

The diamine of dye **144** leads to cationic disazo dyes that color paper in brilliant orange hues [97].

5.1.3.4. Other Trialkylammoniumalkyl-Substituted Coupling Components

The coupling component 2,6-dihydroxypyridine, already an acknowledged component of high-intensity chromophores in disperse dyes, has also been applied successfully to the synthesis of cationic azo dyes. The trialkylammoniumalkyl group may be linked either to the pyridine nitrogen [98] (**149**) [*71873-54-6*] or to C-3 of the pyridine ring [99] (**150**).

149

150

Dyes with cationically substituted derivatives of 2-hydroxy-6-aminopyridine [100], of 2,6-diaminopyridine [101], and of 5-hydroxy-3-methyl-1-phenylpyrazolone [102] as the coupling components have also been described. Coupling components based on 4-hydroxynaphthalimide, which carry the trialkylammoniumalkyl substituent at the imide nitro-

gen, have been used for the synthesis of red cationic azo dyes [103].

Aromatic coupling components may have the trialkylammoniumalkyl linked via a carboxamide group [104], e.g., **151**.

151

Also described as linking groups are ether [105], thioether [106], carbonyl [107], carboxylic ester [108], carbonamide [109–112] and sulfonamide [113] moieties.

Monofluortriazine reactive dyes, in which a trialkylammoniumalkyl group is bound to the heterocycle by an amino group are recommended for blends of polyacrylonitrile with wool, synthetic polyamides or cellulosics [114–116].

5.1.4. Coupling Components with Dialkylhydrazinium Groups

A number of valuable cationic azo dyes contain the dialkylhydrazinium group as the charged moiety of the coupling component. The aromatic amines used as the diazo components are the same as those described for the dyes mentioned in Section 5.1.3.3. The red dye **152** [*4531-45-7*] is formed with 2-chloro-4-nitroaniline:

152

A yellow dye is obtained with 1-amino-2,6-dichloro-4-(*N,N*-dimethylsulfamoyl)benzene, an orange dye with 1-amino-2,5-dichloro-4-(*N,N*-dimethylsulfamoyl)benzene, a yellow brown dye with 1-amino-2,6-dichloro-4-nitrobenzene, a ruby dye with 1-amino-2-cyano-4-nitrobenzene, and a violet species with 1-amino-2,4-dinitro-6-bromobenzene [117].

Red dyes are obtained with 3-phenyl-5-amino-1,2,4-thiadiazole as the diazo component [118].

5.1.5. Coupling Components with Cyclic Ammonium Groups

By reaction of heteroaromatics, such as pyridine, with intermediates that contain anionically displaceable groups, coupling components are obtained that derive their positive charge from a cyclic ammonium group. Alternately, the heterocycle may be linked to the coupling component by other means for later quaternization.

5.1.5.1. Heterocyclically Linked Cyclic Ammonium Groups

Reaction of chloroacetamide with pyridine, followed by condensation with acetoacetic esters in alcoholic sodium hydroxide, leads to a 2,6-dihydroxy-4-methylpyridine that is substituted in the 3-position by a pyridinium moiety. If this is coupled with diazotized aromatic or heterocyclic amines, yellow to red cationic azo dyes (e.g., **153**) [*92691-25-3*] are obtained [119], [120].

153

With aromatic diamines and triamines as the diazo components, cationic substantive disazo and trisazo dyes (e.g., **154**) [*62073-65-8*] are obtained, which are suitable for bulk dyeing of paper [121], [122], [123] or ink-jet printing [124].

A *commercial product* is Cartasol Yellow K-GL (Clariant).

Also known are 2,6-dihydroxypyridine dyes that carry a quaternized benzothiazole [125], benzimidazole [126], or imidazole [127], [128] moiety in the 3- or 4-position.

154

5.1.5.2. Aliphatically Linked Cyclic Ammonium Groups

By reaction of *N*-ethyl-*N*-chloroethylaniline, *N,N*-bis(chloroethyl)aniline, or *N*-ethyl-*N*-chloroethyl-*m*-toluidine with heteroaromatics, especially pyridine, coupling components are obtained that carry cyclic ammonium groups.

155

The red cationic azo dye **155** [*36986-04-6*], obtained with 2-chloro-4-nitroaniline [129], is represented in numerous cationic dye *product lines*: e.g., Maxilon Red 2GL (Ciba), and Yoracryl Red 2G (YDC).

Introduction of a second pyridiniumalkyl residue (**156**) [*24447-84-5*] leads to a brightening of the hue to orange.

156

Here again, all compounds cited in Sections 5.1.3.3 and 5.1.4 are used as the diazo components. In addition, the following have been described as diazo components: 2,5-dichloro-4-nitroaniline (red) [130], 2-chloro-5-trifluoromethylaniline (yellow) [131], 4-nitro-2-trifluoromethylaniline (red) [132], 2-amino-5-trifluoromethyl-1,3,4-thiadiazole (red) [133], 3-methylmercapto-5-amino-1,2,4-thiadiazole (red) [134], 3-methyl-4-nitro-5-aminoisothiazole (blue violet) [135], 2-amino-6-chlorobenzothiazole (red) [136], 3-amino-5-nitro-7-bromobenzisothiazole (blue with a red cast) [137], and 2-amino-4-chloro-3-cyano-5-formylthiophne (blue) [138].

The solubility of these dyes is enhanced when picolines are used for quaternization in place of pyridine [139].

Concentrated aqueous solutions of these dyes are obtained by dissolving the bicarbonate salts of the dyes in aqueous organic acids, e.g., acetic acid [140].

If monoalkylanilines are reacted with vinylheterocycles, especially vinylpyridine, and if the heterocyclic nitrogen is then quaternized, coupling components are obtained that carry the pyridinium component by way of a carbon linkage [141], e.g., **157**.

157

The place of the pyridinium residue may also be taken by the 1,2,4-triazolium [142], the benzimidazolium [143], or the imidazolium [144] moieties. An example is the dye **158** [*47660-05-9*].

158

The cyclic ammonium residue may also be linked to the coupling component via a sulfonamide [145] or an ester [146] group.

A yellow cationic substantive paper dye is obtained by coupling diazotized 2-(4′-aminophenyl)-5-methylbenzothiazole onto an ace-

toacetic arylide, e.g., *N*-aryl-acetoacetamide, substituted by a pyridinium residue [147], or by coupling tetraazotized 4,4′-diaminostilbene with the coupling component of dye **155** [148].

5.1.6. Coupling Components with Condensed Cyclic Ammonium Residues

Heterocyclic compounds wherein the condensed benzene ring is substituted by a hydroxyl or an amino function may be coupled with diazonium compounds and may also be quaternized, either prior or subsequent to the coupling reaction, to yield cationic azo dyes. 1,2-Dialkyl-6-nitroindazolium salts are reduced to the 6-amino compounds and then coupled with diazonium salts of aromatic amines. These dyes (e.g., **159**) color polyacrylonitrile in bright yellow to orange shades [149].

159

6-Amino-1,3-dimethylbenzotriazolium chloride may also be used as the coupling component [150]. By hydrolysis of 6-amino-1,2-dialkylindazolium chloride in dilute sulfuric acid at 180 – 190 °C, a hydroxyl group is introduced into the 6-position. The 6-hydroxy-1,2-dialkylindazolium salt formed is suitable for the generation of mono- [151] (**160**) and disazo dyes [152] (**161**) [*92888-19-2*].

160

161

In a similar manner 6-amino-1,3-dimethylbenzotriazolium chloride may be converted into the 6-hydroxy compound for use as a coupling component [153].

5.1.7. Cyclic Ammonium Residues at the Azo Group

If azo dyes from aromatic diazonium compounds and 1-phenyl-3-methyl-5-pyrazolone or 1-phenyl-3-methyl-5-aminopyrazole are quaternized at the 2-nitrogen of the pyrazole, cationic azo dyes are obtained. A resonance charge exchange is prevented through lack of a donor function at the aromatic moiety [154], [155]. An example is dye **162**.

162

Azo dyes from aromatic diazonium compounds and indolizine derivatives may also be converted into cationic azo dyes by quaternization [156].

5.1.8. Coupling Components with two Different Cationic Residues

Mono- and polyazo dyes have been prepared, in which the coupling component carries at least two different basic and/or cationic groups. Of these, mostly yellow to orange dyes are derived from pyridones with a cyclic ammonium group and an amino- or trialkylammoniumalkyl group. To obtain a technically sufficient affinity to cellulose fibers disdiazo components are preferred either with the same coupling component [157–161] (e.g., **163**) or with different ones [162], [163] (e.g., **164**).

A step further is the connection of two suitable molecules with the help of a dihaloalkane [164], [165] (e.g., **165**).

Dyes of this kind can be used to color anodically generated oxide layers on aluminum [166].

163

164

165

A *commercial product* is Cartasol Yellow K-3GL liq.

Orange, red and violet dyes can be obtained by using as coupling components aminonaphtholsulfonic acids that are connected via the N atom to a 1,3,5-triazine with different aminoalkylamino, trialkylammonium-alkylamino or cyclic ammonium substituents in positions 4 and 6 [167] (e.g., **166**).

166

For example, **167** dyes paper in a scarlet shade [168].

167

Between the N atom of the aminonaphtholsulfonic acid and the triazine ring, spacer groups can be introduced, e.g., aminoaroyl or aminophenylcarbamoyl groups [169], [170].

A different way to synthesize a coupling component with two different basic groups is to react *N*-dibromopropionylaminonaphtholsulfonic acids with dialkylaminoalkylamines to give aziridine derivatives; red dyes are obtained by coupling these with a diazonium salt of *p*-aminoazo-benzene [171] (e.g., **168**).

168

5.2. Cationic Charge in the Diazo Component

Diazo components may contain the cationic charge at amino, dialkylamino, trialkylammonium, or cycloammonium groups.

5.2.1. Diazo Components with Aminoalkyl Moieties

Yellow dyes are prepared by aminomethylation of 2-(4′-aminophenyl)-5-methylbenzothiazole followed by diazotization and coupling with acetoacetarylides. Red cationic dyes are obtained with naphthols or hydroxynaphthoic acid arylides. All are suitable for dyeing paper. The bleachability of these dyes is important for the recycling of waste paper [172]. The aminomethylation of aromatic amines is carried out by reaction with formaldehyde and phthalimide, followed by hydrolytic scission of the phthalic acid residue. By diazotization of 4-methoxy-3,5-bis(aminomethyl)aniline trihydrochloride and coupling with 3-hydroxynaphthoic acid arylides, red cationic substantive paper dyes are obtained [173]. Of importance in the manufacture of cationic substantive paper dyes are reaction products of cyanuric chloride with 2 mol dialkylaminoalkylamine and 1 mol 1,3- or 1,4-diaminobenzene.

Yellow paper dyes (e.g., **169**) are obtained by diazotization of these aromatic amines and coupling with acetoacetarylides [174], [175].

By coupling to derivatives of J acid, substantive dyes (e.g., **170**) are obtained wherein the charge on the sulfonic acid group is more than compensated for by the multiple cationic charges. These dye paper in shades of red [176].

Dyes wherein the dialkylaminoalkyl group is connected to the diazo component via the ester group of anthranilic acid [177–180], a carboxamide [181], a sulfonamide [184], [182] or an ether [183] residue have also been described.

5.2.2. Diazo Components with Trialkylammonium Residues

The trialkylammonium group may be linked to the diazo component either via aromatic substitution or by way of an aliphatic residue.

169

170

5.2.2.1. Aromatically Linked Trialkylammonium Residues

Aminophenyltrimethylammonium chloride was already an important diazo component of the Janus line of dyes. The fastness of these dyes, e.g., **171**, on polyacrylonitrile is enhanced by introduction of halogens. Mono- and dialkylanilines are suitable coupling components [185].

171

Disazo dyes of this series (e.g., **172**) are suitable for dyeing polyacrylonitrile and paper [186].

172

A *commercial product* is Anilan Golden Yellow RL (Ciech).

4-Hydroxynaphthalimide as a coupling component yields cationic dyes that confer an orange-red shade to polyacrylonitrile [187].

Heterocyclic coupling components that have been coupled with diazotized aminophenyltrimethylammonium chloride are 5-hydroxy-1-phenylpyrazole-3-carbonamide [188], 1-alkyl-6-hydroxy-2-pyridone [189], 1-amino-3-hydroxy-isoquinoline [190], and 2,4-diamino-6-hydroxypyrimidine [191]. The trialkylammoniumaryl residue may also be connected to the aromatic diazo component via a sulfone or a sulfonamido function [192]. Disazo dyes in this series (e.g., **173**) [*77901-21-4*] may also be generated from monoazo dyes that still contain a primary amino group by dimerization using phosgene [193], [194] or cyanuric chloride [195].

Coupling with β-naphthol results in a yellow dye suitable for polyacrylonitrile [196], coupling with 2,5-dimethoxyaniline gives an orange dye that is recommended for hair coloration [197].

173

5.2.2.2. Aliphatically Linked Trialkylammonium Residues

The Friedel – Crafts acylation of acetanilide with chloroacetyl chloride yields 1-acetamido-4-chloroacetylbenzene. The trimethylammonium group is introduced by reaction with trimethylamine, followed by hydrolysis of the acetamide group. This diazo component is a constituent of numerous yellow, orange, and red cationic azo dyes. Using diethyl-*m*-toluidine as the coupling component, the lightfast red dye (**174**) [*67905-12-8*] is obtained [198].

174

Introduction of an unsaturated alkyl residue improves the solubility of the dye [199]. *N*-Methyl-*N*-cyanoethylaniline yields an orange dye. The shade is shifted to yellow with a red cast using *N*-cyanoethyl-2-chloroaniline (**175**) [*72208-25-4*].

175

Commercial products are Sevron Yellow 3RL (CKC), and Sumiacryl Yellow E-3RD (Sumitomo).

Use of 2-methylindole as the heterocyclic coupling component has led to commercially important dyes (e.g., **176**) [*25784-16-1*] [200].

176

However, dyes have also been generated from 1-phenyl-3-methyl-5-aminopyrazole [200], 2,4-dihydroxyquinoline [201], 2,6-dihydroxypyridine [202], 2,6-diaminopyridine [203], 2,4,6-triaminopyridine [204], and 3-phenyl-5-hydroxyisoxazole [205]. The solubility of such dyes may be enhanced by introduction of polyether moieties [206].

Cationic dyes with reactive functional groups, e.g., dichlorotriazine or vinylsulfone, suitable for dyeing wool and silk, have also been generated in this series [207]. Bis-cationic dyes, for instance **177**, are suitable for dyeing mixed-fiber fabrics containing acid-modified and unmodified polyamide, whereas the latter does not take up the dye [208].

177

A *commercial product* is Sevron Red YCN (CKC).

The trialkylammonium alkyl residue may also be attached directly to the aryl residue of the diazo component [209]. Dyes that derive from aminomethylated 2-aminonaphthalene and contain acetoacetarylides, naphthols, or pyrazolones as the coupling components are suitable for dyeing paper. An example is the yellow monoazo dye **178**.

178

Disazo dyes are obtained by using coupling components with a primary amino group and dimerization with phosgene [210]. The diazo components are prepared by exhaustive alkylation of aminomethylated 2-aminonaphthalene-1-sulfonic acid, followed by scission of the sulfonic acid group in the presence of mineral acids [211].

The trialkylammonium residue may also be connected to the diazo component by way of an ether [212], a carbonamide [213], [214], a sulfone [215], or a sulfonamide group [216], [217].

Bis-cationic metal-complex dyes are suitable for dyeing leather. Cationic monoazo dyes wherein a trialkylammonium group is linked via a carboxamide group to the diazo component [218] and disazo dyes are known. The latter are prepared from dialkylamino compounds by quaternization using alkylene dibromides. They are suitable for dyeing paper [219].

Azo dyes with 2-(4′-aminophenyl)-5-methylbenzothiazole as the diazo component and carrying trialkylammoniumalkyl residues are suitable for dyeing paper in the same manner as the dyes described in Section 5.2.1 [172], [220]. Also described as carriers of the cationic charge were dialkylhydrazinium residues linked to the diazo component via a sulfonamide [221] or a carboxamide group [222].

5.2.3. Diazo Components with Cyclic Ammonium Residues

The cyclic ammonium residue may either be linked directly to the aromatic ring or attached to the diazo component via an aliphatic residue.

5.2.3.1. Aromatically Linked Cyclic Ammonium Residues

For the preparation of a diazo component that contains a 1,2,3-triazolium residue in the *para* position, *p*-nitrophenylazide in acetone solution is first reacted with acetylene in an autoclave to give 1-(4-nitrophenyl)-1,2,3-triazole. The nitro group is then reduced, the resultant amine acetylated, and the triazole moiety is quaternized with dimethyl sulfate. After hydrolysis of the acetyl group, the resultant amine may be diazotized and treated with ethylcyanoethylaniline to give dye **179** [*47553-94-6*] [223]. The dye colors polyacrylonitrile to a lightfast orange.

179

The triazole moiety may also be linked in the 2-position with respect to the azo linkage [224]. Among cyclic ammonium residues linked via carbon bonds to the aromatic ring of the diazo component have been cited: 1,3-dialkylbenzimidazolium [225], benzothiazolium [226], methylpyridiniumoxazole [227], and pyridinium [228] moieties, linked via nitrogen, as well as the benzotriazolium moiety [229].

5.2.3.2. Aliphatically Linked Cyclic Ammonium Residues

Upon reaction with pyridine azo dyes that carry a chloroethylsulfonamido group in the diazo component form cationic azo dyes, e.g., **180** [*33869-97-5*], which color polyacrylonitrile in brilliant shades [230].

180

The chloroethylsulfonamide may also be reacted with 1,2,4-triazole [231].

Dyes containing the pyridinium group linked to the diazo component via a carboxylic ester function (e.g., **181**) [*32017-47-3*] are obtained by condensation of 4-nitrobenzoyl chloride with chloroethanol, reaction of the ester with pyridine, reduction of the nitro to an amino group, diazotization, and coupling with aromatic amines [232].

181

This dye imparts an orange shade to polyacrylonitrile. The cyclic ammonium residues may also be linked to the diazo component via a carboxamide [233] or an ether group [234] or directly by means of an alkyl residue [235].

5.2.4. Diazo Components with two Different Cationic Residues

Mono- and disazo dyes have been prepared in which the diazo compound carries at least two different basic and/or cationic groups.

Reaction of 2,4- or 2,5-diaminobenzenesulfonic acids with 2-chloro-1,3,5-triazines that are substituted in the 4- and 6-positions by aminoalkylamines and cyclic ammoniumalkylamines, respectively, leads to diazo components which, when diazotized and coupled with derivatives of aminonaphtholsulfonic acids, give rise to dyes for cotton, leather, and especially paper [236]. An example is **182**, which colors paper in a violet hue.

182

183

Reaction of chloromethyl derivatives of 4′-aminophenyl-2-benzothiazoles with e.g. *N′,N″,N‴*-permethyldiethylene-triamine leads to compounds with alkylaminoalkylammonium residues that can be diazotized and coupled with, e.g., acetoacetarylides [237]. An example is **183**, which colors paper in a greenish shade of yellow.

5.2.5. Diazo Components with Aromatic Condensed Cyclic Ammonium Residues

Polynuclear N heterocycles that carry an amino group in the carbocyclic aromatic ring may be diazotized and then joined to azo dyes using aromatic or heterocyclic coupling components. Quaternization at the heterocyclic nitrogen atom may occur before or after coupling. The azo dye **184**, from 2-methyl-5-aminobenzimidazole and 1-phenyl-3-methyl-5-pyrazolone, used in the form of its hydrochloride, dyes paper and leather in clear yellow shades [238].

184

By exhaustive alkylation, dyes are obtained that are suitable for polyacrylonitrile [239].

Introduction of halogen yields dyes with especially valuable properties. A suitable diazo component is 4-amino-6-chlorobenzimidazole. The sequence of diazotization, coupling with aromatic amines, and quaternization gives colorants (e.g., **185**) [*36116-31-1*] that confer fast orange and red shades to polyacrylonitrile [240].

185

Trifluoromethyl-substituted aminobenzimidazole compounds have also been described as diazo components [241].

A bathochromic shift is obtained by using 4-amino-6-chlorobenzotriazole in place of the benzimidazole. The quaternized coupling products with dialkylanilines (e.g., **186**) [*36116-25-3*] dye polyacrylonitrile in red shades with a blue cast [242].

186

Red dyes for polyacrylonitrile are obtained with 6- or 7-aminoindazole as the diazo component [243], (e.g., **187**).

187

Other heterocyclic diazo components that have been used to generate cationic dyes are 4-amino-7-nitrobenzisothiazole [244], 2-methyl-6-aminoquinoline [245], and 5-aminoimidazo[1,2-*a*]pyridine compounds [246].

5.2.6. Cyclic Ammonium Compounds Linked in Meta Position to the Azo Group

Coupling of diazotized N-heterocyclic amino compounds that carry the amino group in the 2- or 4-position to the heterocyclic nitrogen to aromatic or heterocyclic coupling components and subsequent quaternization of the heterocyclic nitrogen leads to diazacyanine dyes (→ Methine Dyes and Pigments).

If the starting materials are heterocyclic amino compounds with the amino group in a meta position, a mesomeric charge exchange is not possible. Therefore, dyes of this type are grouped with the cationic azo dyes.

By coupling of diazotized 3-aminopyridine to 2-naphthol, followed by quaternization, dyes (e.g., **188**) [*41313-61-5*] are obtained that color polyacrylonitrile in fast yellow shades and exhibit excellent leveling characteristics [247].

188

This dye is also recommended for dyeing of human hair [248], as well as the dye containing 2-methylindole as coupling component [249], [250].

5.3. Different Cationic Charges in Both the Coupling and the Diazo Component

A further means to introduce different basic and/or cationic residues (cf. Sections 5.1.8 and 5.2.4) into a dye has been developed by combining diazo and coupling components that each carry different basic or cationic groups. They are synthesized according to the procedures that have been described in Sections 5.1 and 5.2.

Dyes have been prepared that color paper in hues ranging from orange [251] (e.g., **189**, see next page)

to red [252–254] (e.g., **190**)

190

to black [255] (e.g., **191**)

The yellow dye **192**

can be used in ink-jet systems to flocculate anionic pigment dispersions, thus improving the bleedfastness [256], [257].

5.4. Introduction of Cationic Substituents into Preformed Azo Dyes

Cationic substituents may also be introduced into preformed azo dyes. In this manner, mixtures of isomers are obtained which may carry

189

191

192

193

one to four cationic groups in various positions. The multiplicity of isomers is a cause for good water solubility. These dyes are predominantly used for coloring paper.

Reaction of chlorosulfonic acid with mono- [258] or disazo dyes [259] yields sulfonyl chlorides, which can then be transformed into cationically substituted sulfonamides by reaction with dialkylaminoalkylamines. The coupling product of diazotized 2-anisidine with 2-hydroxynaphthoic acid arylide upon such treatment dyes paper red and the azo dye from tetraazotized dianisidine and 1-phenyl-3-methyl-5-pyrazolone gives yellowish orange shades.

Numerous cationic azo dyes are prepared by the action of *N*-hydroxymethylchloroacetamide on azo dyes in sulfuric acid medium, followed by displacement of the reactive chloro substituent by pyridine or trialkylamine. Of special significance for dyeing paper are dyes that are prepared by coupling of diazotized 2-(4′-aminophenyl)−5-methylbenzothiazole to acetoacetarylides, pyrazolones, naphthols [260], or barbituric acid derivatives [261], followed by reaction with *N*-hydroxymethylchloroacetamide and pyridine or *N*-methyl-1,3-diaminopropane [262] . The azo dye obtained by oxidative dimerization of 2-(4′-aminophenyl)−5-methylbenzothiazole may also be subjected to this conversion [263]. Dye **193** colors paper yellow.

194

195

Disazo dyes with β-naphthol as the coupling component give red shades [264].

By removal of the chloroacetyl residue aminomethylated dyes are obtained which are used for coloring paper either as such or upon further alkylation [265]. An example is the yellow dye **194**.

Reaction of azo dyes with formaldehyde and 4-methylimidazole, followed by alkylation, produces cationic azo dyes that dye paper with excellent wetfastness [266]. An example is the disazo dye **195**, which confers a brilliant red shade to paper.

A *commercial product* is Cartasol Brilliant Yellow K-5GL (Clariant).

5.5. Cationic Dyes with Sulfur or Phosphorus as Charge-Carrying Atoms

When dyes containing anionically displaceable groups are reacted with thioethers, cationic dyes (e.g., **196**) are obtained in which the sulfonium moiety carries the charge [267]. The sulfonium group may also be linked directly to the aromatic coupling component [268].

196

By reacting dyes that contain a chloroethyl group with thiourea, the cationic charge may be introduced in the form of an isothiouronium residue (e.g., **197**) [269].

197

To introduce phosphorus as the charge-carrying moiety, dyes that contain haloalkyl groups are reacted with phosphines, such as dimethylphenylphosphine (e.g., **198**) [270].

198

5.6. Dyes with Releasable Cationic Groups

Dyes with releasable cationic groups are converted to water-insoluble dyes when heated in the dye bath. They can then enter textile mate-

rials that are amenable to dyeing with disperse dyes. Using this method, for instance, it is possible to dye polyester materials without having first to generate a finely dispersed form of the colorant with the aid of surfactants. An example of such a releasable group is the isothiouronium moiety [271]. Dyes with isothiouronium groups are also suitable for wool [272].

Reaction of dyes containing a primary amino group with dimethylformamide and an inorganic acid chloride, e.g., phosphoryl chloride, permits introduction of the formamidinium group, which is also scissioned off upon heating in the dye bath (e.g., **199**) [273].

199

A similar reaction occurs with the trialkylhydrazinium moiety obtained by reacting formyl-substituted azo dyes with dialkylhydrazines and subsequent quaternization [274].

6. Developing Dyes

General Survey. There is no standard definition of the term developing dyes. They can include all dyes that are synthesized *on the fiber* or converted there into their final form. In this respect it is possible to distinguish between two main groups:

Developing dyes whose final chromophoric system is synthesized on the fiber with formation of an *insoluble* dye. In the azo dye series, these mainly include the *β-naphthol* and *Naphtol AS dyes*, which are directly synthesized on the fiber; the substrate impregnated with the coupling component is "developed" in a suitable diazonium salt solution. When dyeing or printing the fiber, it is also possible for coupling component and diazo component to be applied simultaneously; not until an aftertreatment is carried out is the coupling process then initiated.

The *diazotization dyes* are also frequently numbered among this group (see Section 4.2.3). As a result of the diazotization of direct dyes with free amino groups and subsequent reaction with suitable coupling components, an azo dye of higher molecular mass with especially good adhesion is synthesized on the fiber.

Developing dyes from another dye class are the *phthalocyanine developing dyes* (e.g., *Phtalogen* dyes (Bayer) → Phthalocyanines).

Developing dyes whose color-imparting structure is synthesized before they are applied to the substrate in the form of *soluble* derivatives; they are converted into an insoluble form by aftertreatment on the fiber.

These include the *polycondensation dyes,* in particular in the azo range, which contain thiosulfate groups (–S–SO_3–) as water-solubilizing groups. In the presence of condensing agents (e.g., sodium sulfide), these compounds undergo polycondensation on the fiber to form insoluble dyes, S–S bridges being formed at the same time (e.g., *Inthion* dyes from Hoechst) [275], [276].

A further example is that of *esterified Naphtol AS* dyes. If azo dyes formed from Naphtol AS components and diazotized color bases are reacted with suitable acylation agents containing sulfo groups, soluble esters of azo compounds, which can be applied to the fiber, are obtained. By saponification in an alkaline medium the esters are then converted on the fiber into insoluble dyes, e.g., *Neocoton* dyes (Ciba); *Tinogenal* dyes (Geigy) and *Neogenol* dyes (Sandoz) [277].

Developing dyes in the second group have never been able to maintain their market position over a lengthy period: they are only mentioned here because their mode of action is of interest from the chemical aspect.

The first group of developing dyes, on the other hand, includes products of major industrial interest. Among all the developing dyes, by far the greatest importance attaches to the insoluble dyes known as Naphtol AS dyes, which are produced on the fiber from 2-hydroxy-3-naphthoic acid amides and other carboxylic acid amides capable of coupling (Naphtol AS components) and suitable diazo components. Only members of this class of compounds are dealt with in detail

in this chapter. In accordance with dyeing and performance aspects they can be divided into

developing dyes for cotton
developing dyes for animal fibers
developing dyes for hydrophobic fibers

The large number of dyeing and printing methods used will be discussed under the keywords → Textile Dyeing and → Textile Printing.

6.1. Developing Dyes for Cotton [5, vol. III, p. 290], [42, vol. 1, p. 502], [278–280]

The principal fields of application are the dyeing and printing of textiles made from cellulosic fibers (natural or regenerated), of which cotton is the main material. Cotton dyeing with developing dyes was being practiced by the end of the 19th century (ice colors); it received a boost with the introduction of Naphtol AS components in 1911. Ten years later, the *Rapid Fast* range (see page 82) made possible an especially simple method of application in the printing of cotton. Cotton dyeing and printing on the basis of developing dyes have now reached such an advanced stage of development, and the dyeings obtained possess such a high quality level, that this class of dye is likely to continue to maintain its market position in the future.

6.1.1. Developing Dyes for Dyeing

6.1.1.1. β-Naphthol Dyes

β-Naphthol dyes are only of historical interest. The initial results achieved in the dyeing of cotton by producing an azo dye on the fiber were patented by TH. and R. HOLLIDAY (1880). They impregnated cotton with an alkaline solution of β-naphthol and, after drying, "developed" the impregnated material by immersing it in an acetate-buffered solution of diazotized α- or β-naphthylamine. In particular the attractive red (para red) obtained by GALLOIS and ULLRICH (1889) using 4-nitroaniline as diazo component was for a long time of importance in the dyeing and textile printing industries. The introduction of further suitable diazo components led to a whole range of shades in these "ice colors" (so-called because of the ice used during diazotization); see Table 12.

Table 12. Amines for the development of cotton impregnated with β-naphthol and shades obtained

5-Nitro-2-aminotoluene	orange
5-Nitro-2-aminoanisole	pink
4-Chloro-2-aminoanisole	scarlet
4-Nitroaniline	red
1-Naphthylamine	bordeaux
3,3′-Dimethoxy-4,4′-diaminodiphenyl (with Cu salts)	blue
3,3′-Dimethyl-4,4′-diaminodiphenyl	brown
Mixture of 4,4′-diaminodiphenylamine and 4-dimethylamino-4′-aminoazobenzene	black

Numerous disadvantages of β-naphthol dyeing (difficulty in obtaining uniform fixation of the coupling component when drying material impregnated with β-naphthol; very limited fastness of the dyeings to light, chlorine, washing, and rubbing) pushed subsequent developments in the direction of the so-called Naphtol AS dyes.

6.1.1.2. Naphtol AS Dyes

In Offenbach (now Hoechst) in 1911, A. WINTHER, L. LASKA, and A. ZITSCHER discovered that instead of β-naphthol it is more advantageous to use the anilide of 2-hydroxy-3-naphthoic acid, listed in the technical literature under its trade name *Naphtol AS;* AS is short for "**A**mid einer **S**äure" (amide of an acid). Compared with that of β-naphthol, the sodium salt of this coupling component possesses the great advantage of having a certain degree of substantivity, i.e., it is absorbed onto the cotton fiber like a direct dye. Uniform fixation on the substrate is thus guaranteed. Moreover, in comparison with β-naphthol, the alkaline solutions of Naphtol AS possess higher air resistance, with the result that the moist cotton fibers impregnated with it can be exposed to air for a prolonged period without undergoing a change. The dyeings obtained on the fiber after development with suitable diazo components are distinguished by a high fastness level.

With the development of a large number of substituted anilides of 2-hydroxy-3-naphthoic acid (known as "β-oxynaphthoic acid arylides") and related compounds as Naphtol AS coupling components (the various products are denoted by additional letters following the AS) and a selection of suitable aromatic amines ("Fast

Color Bases") and their stabilized diazonium salts ("Fast Color Salts") as diazo components, the Naphtol AS dyeing sector underwent rapid expansion.

World production of Naphtol AS components, Fast Color Bases, and Fast Color Salts for dyeing and printing of cellulosic fibers amounts in 1982 to approx. 24000 t (around 6000 t are in addition used for production of azo pigments). This is equivalent to just under 5 % of colorant consumption in the textile sector as a whole, although as a result of a decrease in the proportion of world fibers demand accounted for by cotton, a declining trend can be observed in the percentage rate.

The percentage of Naphtol AS developing dyes in the dyestuffs requirement for textiles made from cellulosic fibers has for years remained constant at around 8 %, although the use of reactive dyes, particularly since the start of the 1970s, has gained increasingly in importance. Around 60 % of Naphtol AS dyes are employed for dyeing, around 40 % in the printing sector.

Table 13 provides a survey of the most important ranges of coupling and diazo components for Naphtol AS dyeing (and printing). The manufacturing countries are combined into three large groups: Western Europe and USA, India and Japan, and the state-trading countries. The first group accounts for about 50 % of production volume, and the other two have approximately equal importance.

The trade names indicate that the spelling Naph*t*ol AS is reserved for the Hoechst range. Naph*th*ol AS components belong to other ranges. The Hoechst spelling is the one mainly used below.

Coupling Components. The following factors were of major importance to the rapid development of numerous new coupling components and their use in cotton dyeing: a simple synthesis process for substituted 2-hydroxy-3-naphthoic acid aryl amides, improved dyeing properties (substantivity, fastness, shades for combinations), and reduction in the sensitivity of the moist impregnated material to air.

2-Hydroxy-3-naphthoic acid can be produced under pressure by reaction of carbon dioxide with the sodium salt of β-naphthol (Kolbe-Schmitt synthesis). The aryl amides are obtained by one-step reaction, 0.4 – 0.5 equivalents of phosphorus trichloride being added slowly at 70 – 80 °C to a mixture of one equivalent each of carboxylic acid and amine in an inert solvent (usually toluene and polychloroalkanes). The reaction mixture is then boiled for some hours and, after cooling, treated with soda to remove the acid. The Naphtol AS compound is filtered off, the solvent recovered. The yield is almost quantitative. The addition of formaldehyde to alkaline solutions of 2-hydroxy-3-naphthoic acid amides improves the air stability of the damp impregnations. The stabilizing action of the formaldehyde can be explained by the reversible formation of hydroxymethyl compounds, the sodium salts of which possess improved hydrolysis resistance.

By varying the substituents in the aryl amide radical and in the hydroxynaphthoic acid moiety, a wide range of coupling components was synthesized. The substituents naturally influence the shade and fastness properties of the azo dyes obtained after development. For example, the introduction of alkoxy groups in the aryl amide radical has a favorable influence on light fastness.

With the commercial products compiled in Tables 14 and 15, the shades obtained with diazotized color bases, such as chloro- or nitroanilines, are almost always orange, red, or bordeaux. Therefore, these Naphtol AS derivatives can also be referred to as "Red Naphtols."

The classification principle used in the Tables is largely that adopted in the Colour Index [7], which is based on the chemical constitution. The trade names are mainly those of the Hoechst range, since as a result of the historical development, the field of Naphtol AS developing dyes is an undisputed domain of this manufacturer. A number of compounds are listed under the different designations of other manufacturers (e.g., *Naphthol, Naphtanilid*). Only in some cases do the letter combinations in the trade names of different firms agree with regard to one and the same compound.

Whereas with 2-hydroxy-3-naphthoic acid amides, only red shades (apart from a few reddish brown shades) can be obtained by varying the aryl amide radical in combination with simple diazo compounds, coupling components derived from *o*-hydroxycarboxylic acids of other ring systems yield brown and black shades. Here, derivatives of carbazolecarboxylic acid

Table 13. Trade names of important coupling components and diazo components for Naphtol AS dyeing and their manufacturers

Country	Manufacturer	C. I. Azoic Coupling Component	C. I. Azoic Diazo Component	
			Bases	Stabilized salts
Germany, Fed. Rep.	Hoechst	Naphtol AS-	Echt-Base	Echt-Salz Azanil-Salz Variaminblau
Switzerland	Rohner	Naphtanilid	Fast Base	Diazo Fast

and dibenzofurancarboxylic acid are of particular importance (see Table 16).

Yellow dyeings are not obtainable by combination of *o*-hydroxyarylcarboxylic acid amides with color bases. The coupling components used for yellow shades are derived from acetyl- and benzoylacetic acid amides. Although in the chemical sense they are therefore not naphthol derivatives, they are classified as Naphtol AS components and in accordance with their coloristic properties are often called "Yellow Naphtols" (Table 17).

In contrast to the red Naphtols (Tables 14 and 15) and heterocyclic coupling components (Table 16), the yellow Naphtols are stable in alkaline solution; therefore, no addition of formaldehyde is necessary, and because of side reactions it is even inadmissible.

Apart from the coupling components listed in the tables, mention should also be made of those that as a special structural characteristic contain azo groups, e.g., *Naphthol AS-BN* (Blackman Uhler) (*C. I. Azoic Coupling Component 43,* exact constitution not as yet published).

An interesting development during the sixties was *Naphtol AS-FGGR* (Bayer) (*C. I. Azoic Coupling Component 108*): the condensation product of a blue dye (nickel phthalocyanine sulfochloride) and a coupling component in the yellow range (aminophenyl pyrazolone derivative) yields in combination with suitable diazo components brilliant yellowish greens with outstanding light fastness [281]. Since the coupling component possesses virtually no affinity for the cellulosic fiber, the product was mainly used for textile printing by the Rapidogen process (see page 83). Green dyeings are now obtained almost exclusively by combination of phthalocyanine developing dyes, e.g., *Phtalogen* (Bayer), with yellow Naphtol AS dyes.

Diazo Components. A large number of diazotizable aromatic amines are available for azoic coupling with the coupling component (see Table 18). The diazo components are sold either as nondiazotizable bases, so-called "Fast Color Bases" (both as free amines, if they are stable and nontoxic, and as hydrochlorides or sulfates), or as stabilized diazonium salts, so-called "Fast Color Salts" (for trade names see Table 13). The diazonium compounds are isolated ("precipitated") in the form of chlorides, sulfates, hydrogen sulfates, double salts of zinc chloride, fluoroborates, oxalates, and neutral or acid 1,5-

naphthalenedisulfonates and other aromatic sulfonates, the optimum conditions depending on the type of base. Final stabilization is achieved by mixing ("adjusting") with inert salts (usually aluminum sulfate). For further details → Diazo Compounds.

With the diazo components, too, the chemical constitution naturally has a great influence on fastness properties and shade of the dyeing obtained with a coupling component. It has been found that negative substituents (halogens, nitro, nitrile, RO_2S, and, in particular, CF_3 groups) in the aromatic nucleus exert a favorable influence on light fastness. In addition to suitable substituted aniline derivatives, which in combination with 2-hydroxy-3-naphthoic acid amides almost without exception yield red shades (orange, red, bordeaux), color bases have been developed that can be combined with the same Naphtol AS components to give blue and violet shades. Here, chief mention can be made of: *N*-aroyl-*p*-phenylenediamine derivatives, which contain no negative substituents, and 4-aminodiphenylamine derivatives. With compounds of the latter type (*Variamin Blue* bases and salts; Hoechst) attractive blue shades are obtained and in combination with *Naphtol AS-GR* (*C. I. Azoic Coupling Component 36,* 37585; see Table 16) green dyeings as well. 4-Aminoazobenzene derivatives produce black dyeings in combination with Red Naphtols.

The diazo components compiled in Table 18 have been classified first by coloristic aspects (shades) and second by constitutional characteristics (in accordance with the Colour Index [7]). The shades specified in the trade names relate,

with only a few exceptions to the dyeings obtained with Red Naphtols.

Basically speaking it is possible for the dyer to combine any aromatic base with any Naphtol AS component. However, only a limited selection of all conceivable combinations fulfil the preconditions for a coloristically high-grade dyeing. The dyeings generally possess high fastness to rubbing, washing, chlorine, and light. Many of the Naphtol AS dyes obtained on the fiber attain fastness levels of Indanthren dyes, without being chemically related to these compounds, which are usually polycyclic (examples see Table 19).

Other Developments. A new development in Naphtol AS dyeing, which commenced at the start of the 1960s, utilized the tendency of certain azo dyes to form metal complexes. Heteroaromatic amines that fulfil certain structural pre-conditions (see Section 2.3.4) are used as diazo components and the dyeings obtained on the fiber with Naphtol AS components by the usual method are converted into especially lightfast metal complex dyeings by aftertreatment with heavy-metal salts (copper, cobalt):

A further development concerns improvement in the dyeing methods. The conventional two-bath technique (impregnation of the material with the alkaline solution of the substantive coupling component, removal of the excess, and subsequent treatment with the diazonium salt solution) can often be considerably simplified and shortened by using the so-called *one-bath method:* a highly substantive Naphtol AS impregnating component and the developing component are prepared together in one bath. Not until the acid has been added is formation of the dye initiated. Diazo components suitable for this purpose consist of a diazoamino compound not

capable of coupling in the neutral and alkaline range, which in the presence of acid is regenerated into the active diazonium salt (see Section 6.1.2). The addition of dispersing agents to the developing component ensures that the insoluble dye formed in the liquor remains in colloidal dispersion and can be removed during the subsequent washing process (*Azanil* Color Salts from Hoechst) [285–288].

The introduction of *liquid brands* of azoic coupling components and azoic diazo components results in a considerable simplification of important steps in the dyeing and printing with Naphtol AS developing dyes. The former are 25 – 45 % solutions of monoalkali salts of Naphtol AS components in high-boiling alcohols (usually ethylene or diethylene glycol) miscible with water. These highly concentrated molecular solutions with good storage stability permit dust-free handling of the coupling component and enable ready-to-use impregnating baths to be prepared especially quickly by simply pouring in the relevant liquid brand into aqueous diluted sodium hydroxide solution. The liquid brands of the diazo components are either molecular solutions or dispersions: aromatic amines with low melting points (down to approx. 80 °C) are dissolved as free bases in monoalkyl ethers of diethylene glycol (occasionally with the addition of dimethylsulfoxide or *N*-methylpyrrolidone); higher melting amines (*mp* above 100 °C) can in the presence of suitable surfactants and other auxiliaries (ethylene glycol, glycerol, or sorbitol) be processed in more highly concentrated dispersions. Apart from dust-free handling, all liquid brands of diazo components are distinguished by particularly rapid and complete diazotizability without troublesome side reactions [289] (see also page 82).

6.1.2. Developing Dyes for Printing [5, vol. III, p. 290 – 301], [278–280], [290]

For details of the printing method → Textile Printing.

Two-Stage Printing Processes. As with the dyeing of cotton fibers, two-stage methods can also be employed when printing. Depending on whether the coupling component (as sodium salt) or the diazo component (as diazonium salt) is applied during the printing process, a distinction is made between naphtholate printing processes and base printing processes.

In the *naphtholate printing process,* the sodium salts of the Naphtol AS compounds in the form of aqueous, thick pastes (additions of high-swelling, nonionic or anionic polysaccharides) are printed on the textile material and then developed as azo dyes on the fiber by treatment with the solution of a diazotized base.

Naphtholate printing has always been of only secondary importance.

In the so-called *base printing process,* the cellulosic material is first impregnated with the solution of a sodium naphtholate and, after drying, the thickened solution of the diazotized Fast Color Base is printed onto the material.

In contrast to cotton dyeing, with the wide diversity of Naphtol AS derivatives that are used, price, coloristic, and substantivity reasons dictate that only two components capable of coupling are in the main used for impregnation of the textile to be printed: *Naphtol AS* (*C. I. Coupling Component 2,* 37505, see Table 14) as red component and *Naphtol AS-G* (*C. I. Coupling Component 5,* 37610, see Table 17) as yellow component. The cotton impregnated with the sodium salts of these Naphtols by padding and subsequent drying has good, if only limited, stability when stored in a cool, dark place. Because of their low substantivity for the cellulosic fiber, Naphtol AS and Naphtol AS-G additionally satisfy the important requirement that after the base printing process they can be completely washed off again from the unprinted parts.

By combining the two Naphtols with numerous azoic diazo components, a relatively wide range of printed shades is possible. The addition of Naphtol AS enables shades in the or-

* Mainly those of the Hoechst range

ange, scarlet, red, bordeaux, violet, navy blue, and black range to be obtained, Naphtol AS-G is used in the yellow to brown range. If higher requirements must be met with regard to light fastness, Naphtol AS-G can be replaced by *Naphtol AS-IRG* (*C. I. Coupling Component 41,* 37613, see Table 17).

Right into the 1940s, the base printing process enjoyed considerable industrial importance, but in comparison with the one-stage process it then receded into the background. The development of reactive dyes resulted in a worldwide revival of the two-stage base printing process, because vinyl sulfone dyes, in particular, can in many cases be applied together with color salts or diazotized color bases. The possibility of printing a broader range of shades on cotton, which had long been desired, can thus be achieved [291].

The additional combination of the yellow to golden yellow azoic developing dyes with the blue phthalocyanine developing dyes, in particular with a cobalt-phthalocyanine derivative of clear, dark blue color (*C. I. Ingrain Blue 5,* Phtalogen Blue IBN [*37370-33-5*] from Bayer) makes it possible to match deep green shades and thus close a gap in the color range.

These subsequent developments have resulted in the base printing method acquiring considerable importance, in particular for so-called African and Java prints.

Other Developments. In the conventional diazotizing process, the differences in the reactivity of aromatic amines frequently lead to the uncontrolled release of nitrous gases and undesired side reactions, in spite of the fact that ice is used. With the use of liquid brands (see page 75) instead of the powder of the free base, it was possible to increase the rate of diazotization considerably and to eliminate the formation of byproducts. A further refinement of this technique led to an especially elegant variation of the base printing process, the so-called *DIP process* ("**D**iazotization **i**n the **p**aste"): the aqueous – alcoholic dispersion or molecular solution of the base is stirred into a paste of sodium nitrite which without being cooled is then mixed with the aqueous paste of a medium-strong acid (it is best to use phosphoric acid). Diazotation is completed quickly without any formation of nitrous gases. The diazo salt paste obtained no longer needs to be buffered; during the subsequent printing process it couples rapidly and completely with the Naphtol in the impregnated fabric [289], [292].

The possibility of diazotizing mixtures of different azoic diazo components at the same time in a single paste has proved to be a particular advantage of the diazotization process described. The use of mixed coupling products thus opened up a further possible method of shade matching.

One-Stage Printing Processes. Especially simple methods of printing cotton fibers were developed using the one-stage direct printing process. In this technique, the diazo component in the form of a stabilized diazo compound, i.e., not initially capable of coupling, is applied at the same time as the coupling component and coupling is then initiated by a damp aftertreatment in an acid medium or by acid, or frequently also neutral steaming.

Three different diazo derivatives are employed in textile printing as stabilized diazo compounds (a more appropriate term is concealed diazo compounds): antidiazotates, diazo sulfonates, and diazoamino compounds (for properties and production → Diazo Compounds).

Combinations with diazoamino compounds were of particular industrial importance, but with the appearance of the reactive dyes, they, too, receded into the background.

Because of its relatively complicated chemical background, the one-stage printing process must be dealt with in somewhat more detail.

Combinations with Antidiazotates. Unlike the unstable syndiazotates, the stable antidiazotates do not couple with alkaline β-naphthol solution, or if so only very slowly.

Not until the acid treatment is carried out is the diazonium ion formed with subsequent rapid azo coupling. This fact acquired importance in textile printing, diazotates of weakly basic, mainly chlorinated amines being used in

particular, because of their good stability and development ability.

Antidiazotates are obtained in a simple manner by introducing a diazonium salt solution into concentrated aqueous alkali and heating to temperatures above 100 °C, whereby the syndiazotate formed initially is rearranged into the anti compound.

Mixtures of sodium salts of 2-hydroxy-3-naphthoic acid amides and other coupling components in the Naphtol AS range with antidiazotates in the form of pastes and powder brands have been marketed since 1921 as *Rapid Fast* dyes. If the fibers impregnated or printed with them undergo an acid aftertreatment, regeneration of the active diazonium salt and coupling of the azo dye take place on the substrate. A number of combinations and the shades obtained with them are compiled in Table 20, considerable importance attaching in particular to *Rapid Fast Blue BN*.

Rapid Fast Bordeaux RH	Fast Red R Base	Naphtol AS-BS
Rapid Fast Blue BN	Fast Blue B Base	Naphtol AS
Rapid Fast Brown IBH	Fast Red R Base	Naphtol AS-LB

The generally limited storage stability of the mixtures has proved to be a disadvantage of the process described, because slow splitting of the antidiazotate takes place in the alkaline printing paste.

Combinations with Diazosulfonates. Diazosulfonates $Ar{-}N{=}N{-}SO_3^-$, obtained by reaction of diazonium salts with sulfites, do not couple in their stable anti form with 2-hydroxy-3-naphthoic acid amides, or if so only slowly. The diazonium compound capable of coupling is reformed when exposed to light or when the temperature increases.

The *Rapidazol* dye range introduced in 1932 utilizes this property: ready-to-use mixtures of diazosulfonates, in particular from the 4-aminodiphenylamine range (*Variamin Blue* bases, see Table 18), with coupling components of the Naphtol AS type are printed on the fiber and then developed into azo dyes in neutral steam, especially in the presence of oxidizing agents.

In spite of its limited color scale, the range, with its high-quality blue and black brands, was a welcome addition to the diazotate mixtures. It was especially important at a time when no diazoamino compounds capable of being developed in a neutral medium were available.

Combinations with Diazoamino Compounds [6, p. 177]. Among the Naphtol AS combinations for printing, it is the stable diazoamino compounds that are mainly used. Since the release (1930) of the first *Rapidogen* dyes up to the worldwide introduction of the reactive dyes, standardized mixtures of these combinations had enjoyed major industrial importance. The most important commercial ranges based on diazoamino compounds are compiled in Table 21.

Poland		Pologen

Diazoamino compounds (further details → Diazo Compounds) are obtained by reacting

a diazonium salt (**200**) with a primary or secondary aliphatic or aromatic amine:

In the case of aromatic amines, the diazoamino compound only forms if blocking or deactivation of the coupling positions in the aromatic nucleus prevents the formation of an aminoazo compound. The reaction (13) is reversible, i.e. the addition of acid causes the diazoamino compounds to be split again into their initial components. If a primary amine R–NH_2 (**201**) is used, the resulting triazene (**202**) is in balance with its tautomer (**202a**):

The splitting process can thus lead to the formation of a new diazonium salt (**201a**) ("rediazotization").

The tautomer equilibrium **202** ⇌ **202a** is dependent on the nature of the two radicals Ar and R: as the basicity of amine Ar−NH_2 (**200a**) increases and that of amine R−NH_2 (**201**) decreases, the equilibrium shifts in favor of the diazoamino compound (**202**), which is split in the desired manner to form the original diazonium salt.

For practical usage as a stabilized diazo compound in printing combinations, only those diazoamino compounds are suitable that satisfy the following conditions:

Well-defined splitting without rediazotization.
No possibility for the diazonium salt obtained after splitting to couple with the amine component.
Solubility of the diazoamino compound in water.

As amine component, the so-called stabilizer, use is thus generally made of non-diazotizable secondary amines, or the equilibrium is influenced by 2nd order substituents in the stabilizing amine (decreasing basicity). When aromatic stabilizers are used, the *o*- and *p*-position in relation to the amino group is usually blocked by substituents, with the result that after splitting of the diazoamino compound no coupling to aminoazo products can occur. If a possible coupling position is free, the azo coupling is handicapped by the deactivating influence of carboxylic acid or sulfonic acid groups. These substituents additionally impart the desired water solubility to the diazoamino compound used in the printing combinations.

Stabilizers frequently used are sarcosine, *N*-methyltaurine and anthranilic acid derivatives:

The diazoamino compound (for further details → Diazo Compounds) is generally obtained by adding a diazonium salt solution to the neutral or alkaline solution of the stabilizer in the form of its sodium salt. The reactivity of the diazonium salt determines the speed of the reaction. The diazoamino compound precipitated or salted out is filtered, dried, ground, and adjusted with the sodium salt of a Naphtol AS component.

After the textile fabric has been printed with the printing combination, the dyeing is developed by acid steaming (in the presence of acetic and formic acid vapors). The reaction of the two soluble components on the fiber to form the insoluble azo dye is illustrated by the example of *Rapidogen Red GS* (**205**).

203 **204**

203: Diazoamino compound of Fast Red KB base and sarcosine.
204: Naphtol AS-D

The diversity of combinations on the market makes it possible to obtain dyeings of any shade from greenish yellow through orange, scarlet, red, bordeaux, violet, blue, green to black.

The need for acid development has occasionally proved to be a certain disadvantage. This step can be avoided by using a steam-volatile organic base, such as diethylaminoethanol, instead of the alkali employed in the Naphtol AS diazoamino combinations. During neutral steaming, the alkali component in the printing mixture then escapes and azo coupling takes place, especially in the presence of salts which in the steam undergo hydrolysis to form compounds with an acid reaction (e.g., ammonium or pyridinium salts). Selection of suitable modified stabilizers, such as **206** or **207**, also enables the splitting tendency of the diazoamino compounds to be so carefully "counterbalanced" that the relevant printing combinations can be developed in neutral steam (*Rapidogen N, Neutrogen dyes*, etc., see Table 21).

206

207

For use of diazoamino compounds for the dyeing of cotton, see page 77, and of synthetic polyamide fibers, see Section 6.3.

6.2. Developing Dyes for Animal Fibers

Compared with the dyeing and printing of hydrophilic cellulosic fibers, the dyeing of animal fibers (protein fibers) with products in the Naphtol AS range has never attained industrial importance. In this connection, mention is made here only of the Hoechst ranges of *Ofna-Lan* and *Rauna* dyes, which are no longer on the market and were used for the dyeing of wool – cellulosic blends and furs. The problem with this dyeing method proved to be the alkalinity of the impregnating baths (alkaline solutions of the Naphtol AS coupling components), because of the sensitivity to hydrolysis of the peptide compounds of animal fibers [293].

Pure silk can be dyed in the same way as cellulosic fibers, since, unlike wool, silk is largely insensitive to alkali.

6.3. Developing Dyes for Hydrophobic Fibers

Naphtol AS dyes have also been used commercially for dyeing hydrophobic synthetic fibers, particularly polyester and polyamide. Two methods were developed [294]:

In the *modified azo process*, the coupling component and the azoic diazo component are applied to the fiber consecutively or from an aqueous bath at 80 – 130 °C, if necessary in the presence of a carrier, and the fiber impregnated by this means is then treated with nitrous acid. Development of the dyeing takes place with diazotization and simultaneous coupling.

Products are being introduced that in the optimum mixture ratio contain selected combinations of coupling and diazo components capable of development (*Intramin* dyes, Hoechst; *Ronasyn* dyes, Rohner). The process only gained importance in the inexpensive black dyeing of polyester fibers (*C. I. Azoic Black 16,* e.g., *Intramin Black G*, Hoechst). Multicolored shades are more advantageously obtained with disperse dyes.

When *using diazoamino compounds* (so-called *Ofnaperl process*, Hoechst) a suitable diazoamino compound is added to the alkaline bath, in which the Naphtol AS component is dissolved. After the fiber is impregnated in this bath at 60 – 80 °C, the development process is initiated in the warm acid bath by liberating the concealed diazonium salt. Unlike the components of the printing combination, the diazoamino compounds used contain no carboxylic acid or sulfonic acid groups; they have only limited solubility in water but must be readily dispersible (*C. I. Azoic Diazo Components 127, 128*, and *130*, *Ofnaperl* Salts, Hoechst). The process has proved especially effective for the dyeing of polyamide fibers (perlon, nylon).

7. Disperse Azo Dyes (→ Disperse Dyes)

Disperse dyes are dyes sparingly soluble in water which are used for dyeing synthetic fibers. The dyes are added to the aqueous dye bath in finely dispersed form and are uptaken out of this dispersion by the hydrophobic fiber.

The fiber hereby represents the organic phase, in which the disperse dyes are more soluble than in the aqueous dyebath.

About half of all disperse dyes belong to the azo range. Originally developed for cellulose acetate fibers, disperse dyes are nowadays used in large quantities for dyeing polyester fibers.

8. Azo Pigments (→ Pigments, Organic)

Pigments are coloring matters that are practically insoluble in the application media (DIN 55944). Coloring matters are all color-spending materials according to DIN 55945.

Azo pigments are the most important class within the group of organic pigments. Mono- and disazo pigments are the two main ranges.

Whereas in English a strict differentiation exists between pigments (insoluble coloring matters) and dyes (soluble coloring matters) in German some confusing terms are still occasionally used, e.g., "Pigmentfarbstoffe", "Körperfarben", "Farbkörper", "Lackfarbstoffe". These terms should be discontinued and only "pigments" and "dyes" used.

Azo pigments, like all other organic pigments, serve for the coloration of polymeric materials such as plastics, elastomers, rubber, paints and other coating materials, and for printing pastes. The relatively inexpensive azo pigments have gained noticeable importance due to the rapid economic and industrial development in the past three decades.

9. Alcohol- and Ester-Soluble Dyes

With the exception of the blue copper phthalocyanine derivatives, these products are azo dyes soluble in polar solvents, such as alcohols, glycols, esters, glycol ethers, and ketones. Dyes soluble in alcohol and esters are used in protective lacquers for the transparent coating of metal (aluminum) foils and other materials, such as wood (greening lacquers); in flexographic inks for the printing of metal foils, cellophane and paper; as well as for the coloration of cellulose esters, celluloid, and poly(vinyl acetates), and, in the office supplies sector, for stamping inks and pastes for pressure recorders. See Table 22 for important product ranges.

Table 22. Designation of important alcohol- and ester-soluble dye ranges

Manufacturer	Range
BASF	Neozapon, Zapon Fast
Bayer	Irisol Fast
Ciba-Geigy	Grasol Fast, Irgacet, Oracet, Orasol
GAF	Azosol Fast
ICI	Methasol
Sandoz	Savinyl

In modern formulations for foil lacquers, dyes with better solubility in esters are given preference over the older products, which are mainly soluble in alcohols. As regards chemical constitution, there is no precise delineation between alcohol- and ester-soluble dyes, nor between these two groups and the fat- and oil-soluble dyes described in Chapter 10.

In accordance with chemical aspects, the most important alcohol- and ester-soluble azo dyes can be divided into three groups:

1 : 2 Metal complexes of (mainly mono-) azo dyes, without sulfonic or carboxylic acid groups, and trivalent metals (→ Metal-Complex Dyes).

The metals chiefly suitable are chromium and cobalt, as well as nickel, manganese, iron, or aluminum. Diazo components are mainly chloro- and nitroaminophenols or aminophenol sulfonamides, coupling components are β-naphthol, resorcinol, and 1-phenyl-3-methylpyrazolone (5). Formation of a complex from an azo dye and a metallic salt generally takes place in the presence of organic solvents, such as alcohols, pyridine, or formamide. An example is *C. I. Solvent Red,* 12715 (**208**) [*33270-70-1*].

208

1 : 1 Metal-complex azo dyes that contain sulfonic acid or carboxylic acid groups and are present in the form of internal salts. Here, azamethin – metal complexes are also of importance. An examples is *C.* I. Solvent Yellow 32, 48045 (**209**) [*61931-84-8*].

209

In the case of *C. I. Solvent Orange 56,* similar to 18745 : 1 [*13463-42-8*], also a metal complex, diazotized 2-hydroxy-3-amino-5-nitrobenzene sulfonic acid is coupled to 1-phenyl-3-methylpyrazolone (5).
C. I. Solvent Yellow 82, similar to 18690, is a 1 : 1 metal complex of the azo dye obtained from anthranilic acid and 1-phenyl-3-methylpyrazolone (5).
Reaction products of acid azo dyes, acid 1 : 1 metal-complex azo dyes, or 1 : 2 metal complex azo dyes without acid groups, with organic bases or cationic dyes.

Cyclohexylamine, dodecylamine, and sulfonium or phosphonium compounds serve as bases, whereas derivatives of the xanthene range (rhodamines) are mainly used as cationic dyes. Example: *C. I. Solvent Red 109* [*53802-03-2*] is composed of *Solvent Yellow 19*, 13 900 : 1, (**210**) [*10343-55-2*] and *Solvent Red 49*, 45 170 : 1, (**211**) [*81-88-9*]:

210

211

These dyes are saltlike compounds of a metal-complex azo dye acid and a base.

10. Fat- and Oil-Soluble Dyes

Fat- and oil-soluble dyes are also soluble in waxes, resins, lacquers, hydrocarbons, halogenated hydrocarbons, ethers, and alcohols, but not in water. It is not possible to differentiate clearly between them and the alcohol- and ester-soluble dyes (see Chap. 9).

Table 23. Designations of important fat- and oil-soluble dye ranges

Manufacturer	Range
Amer. Cyanamid	Calco
BASF	Sudan
Bayer	Ceres
Bitterfeld	Sudan
Du Pont	Oil
Ethyl Corp.	Oil Soluble
Hoechst	Fat
ICI	Waxoline
Siegle	Sico Fat
Williams	Oil

With the exception of the blue anthraquinone derivatives, all fat- and oil-soluble dyes belong

to the azo range. These azo dyes are generally based on simple components. According to their degree of solubility they usually contain hydroxy and/or amino groups, but not sulfonic acid and carboxylic acid groups. See Table 23 for important product ranges.

As examples, mention can be made of some of the most important fat- and oil-soluble azo dyes produced on an industrial scale: *C. I. Solvent Yellow 56,* 11021 (**212**) [*2481-94-9*]

212

C. I. Solvent Yellow 14, 12055 (Orange) (**213**) [*842-07-9*]

213

C. I. Solvent Yellow 16, 12700 (**214**) [*4314-14-1*]

214

C. I. Solvent Red 23, 26100 (**215**; R = H) [*85-86-9*]; *C. I. Solvent Red 24,* 26105 (**215**; R = CH_3) [*85-83-6*]

215

C. I. Solvent Black 3, 26150 (**216**) [*4197-25-5*]

216

The products are sold in powder form, as granules, or as flakes, and some dyes also as liquid brands. The liquid brands are highly concentrated solutions of fat-soluble dyes in aromatic hydrocarbons, in some cases also solvent-free 100 % liquid products.

Fat- and oil-soluble dyes are used on a large scale in a wide variety of industrial sectors. Main fields of application are the coloration of products in the mineral oil and plastics industries, as well as of wax products (e.g., candles, shoe polish, floor polishes).

Mineral oil products (fuels, fuel oil, lubricating oils, and greases) are colored as a means of distinguishing between different grades (supergrade petrol) or for compulsory identification, e.g., of diesel and fuel oils, for duty purposes. The plastics industry values the fat- and oil-soluble dyes for the highly transparent colorings, usually with very good light fastness, that are obtainable with them. Products in this dye class are most frequently used for the coloration of polystyrene, as well as for incorporation in polymethacrylate and unsaturated polyester casting resins.

An interesting factor is the high degree to which the light fastness of fat- and oil-soluble dyes is dependent on the medium colored. Whereas, for example, 0.05 % colorations of the dye *Solvent Yellow 56,* 11021, in candle materials possess only moderate light fastness (step 3 on the eight-step Blue Scale), transparent colorations in polystyrene are distinguished by outstanding light fastness (step 8).

Other fields of application are the pyrotechnics industry (high sublimation tendency of the dyes), the office supplies industry (inks for felt-tip pens, oil-based stamping inks), the lacquers industry (especially coloration of transparent lacquers on aluminum foil) and the cosmetics industry (approval restricted to a few products).

The history, production, analysis, and uses of barium and barium compounds are described. Barite (barium sulfate) is the most important barium compound. Most of its use is in drilling fluids for crude oil and natural gas exploration. Use of pure barium sulfate is, e.g., as a filler and extender and as a contrast agent in X-ray diagnosis. Barium carbonates are mainly used to remove sulfate ion impurities and to introduce barium oxide into special fine glassware such as cathode tube television screens. The production pathway of barium and barium compounds typically starts from barite. Volatile barium compounds impart a pale green color to flames, and this is an effective, simple qualitative test for barium.

1. Barium Metal

Barium belongs to group 2 of the periodic table and is one of the alkaline-earth metals. Of the elements barium is 19th in atomic abundance. Its average content in the earth's crust is estimated to be 250 g/t [10].

The soft, silver-colored metal is very reactive and does not occur free in nature. However, its compounds are widely distributed. Its major minerals are barium sulfate (barite, heavy spar) and barium carbonate (witherite). Barium sulfate occurs in large deposits throughout the world, and it is the most important raw material for all other barium chemicals. The total annual world production of barium compounds is estimated around 6×10^6 tons. The total world reserves are thought to be around 450×10^6 tons [11].

DAVY first prepared barium metal by electrolyzing mixtures of barium oxide and mercuric oxide and subsequently evaporating the mercury in the year 1808 [12]. He proposed the name barium. The principles of the reduction of the oxides of alkaline-earth metals with aluminum were described by MALLET [13] as early as 1878, but GUNTZ [14] is considered to be the first who obtained a considerable amount of barium of good purity by aluminothermic reduction of the oxide.

1.1. Physical Properties

Barium has a body-centered cubic crystal structure at standard temperature and pressure. It is a soft, silvery white metal of medium specific weight and good electrical conductivity (see Table 1). Ultrahigh-purity barium is described as slightly golden yellow [15]. The color changes into silvery white as soon as the surface is contaminated. It is not easy to obtain samples of ultrahigh purity, and therefore accurate measurements of some physical properties of barium metal are difficult to carry out. In fact, the values for some physical properties are still the subject of controversy.

1.2. Chemical Properties

Barium is clearly metallic and is strongly electropositive. In all of its compounds it has an oxidation state of +2. Barium is very reactive, and its compounds have high energies of formation. Barium forms stable salts with nearly all oxoacids. Table 2 summarizes the physicochemical properties that are associated with the chemical properties of the element.

Generally speaking, barium is more reactive than magnesium, calcium, or strontium. On heating, it readily combines with the halogens in strongly exothermic reactions. It also reacts with the chalcogens to form BaO, BaS, BaSe, and BaTe [16]. These compounds are also formed by reduction of the carbonate, sulfate, selenate, or tellurate [17, pp. 917–934]. Barium combines with oxygen even at room temperature. Therefore, the metal must be protected from oxidation by storage under paraffin oil or an inert gas. A series of phosphides can be isolated [18]. Reaction of barium with nitrogen starts at about 250 °C. The compound Ba_3N_2 is formed [17, pp. 917–934], [19].

Silicon reacts with barium at 1150 °C to form the silicides BaSi, $BaSi_2$, and Ba_3Si_4 [20]. Barium combines with carbon to form the carbide BaC_2 [21]. At moderately elevated temperatures barium reacts with hydrogen to form the hydride BaH_2 [17, pp. 921–922]. Barium reacts vigorously with water, liberating hydrogen, to form the strong base barium hydroxide. The metal reacts similarly with alcohols to form the alkoxides and hydrogen. Barium metal is used for synthesis of barium dipivaloylmethanate as the basic compound for the preparation of high temperature superconducting films by the chemical vapor deposition technique [22]. Barium dissolves readily in liquid ammonia. The blue or black solutions contain amine complexes such as $Ba(NH_3)_6$. Evaporation of the solvent leaves residues of barium amide, $Ba(NH_2)_2$, imide, Ba(NH), and nitride, Ba_3N_2 [23, 24].

There is an increasing number of organobarium compounds. Alkyl- and arylbarium halogenides, RBaX, as well as dialkyl- and diarylbarium, R_2Ba, have been synthesized [25, 26]. For a comprehensive revue see [27].

Barium forms many alloys, and many binary phases have been described [28]. Nevertheless, only the system barium – aluminum has commercial importance.

1.3. Production

On an industrial scale barium metal is produced in a vacuum by reduction of its oxide with aluminum:

$$4\,BaO + 2\,Al \rightarrow 3\,Ba + BaAl_2O_4$$

The two-stage process is similar to that for calcium. The raw material is barium oxide (see Section 2.7).

The barium oxide is mixed with aluminum granules, and the mixture briquetted and charged into long tubular retorts of heat-resistant steel. These are evacuated and heated to ≈ 1100 °C at the end containing the charge, while the other end is kept cool. Molten aluminum and aluminum vapor react with the solid barium oxide, releasing barium vapor, which condenses in the cooler part of the apparatus [29], where it is collected and cast into chill molds under argon.

$BaAl_4$ is an intermediate [30], and the net reaction is actually the sum of three reactions:

$$3\,BaO + 14\,Al \rightarrow 3\,BaAl_4 + Al_2O_3$$

$$8\,BaO + BaAl_4 \rightarrow 7\,Ba + 2\,BaAl_2O_4$$

$$BaO + Al_2O_3 \rightarrow BaAl_2O_4$$

In the laboratory the aluminothermic reduction of barium oxide is also the most useful method of preparation [7, pp. 920–921], [23, 31 – 34]. It is also the method of choice for preparing of high-purity samples [35].

Silicon powder can be used to reduce barium oxide, but somewhat higher temperatures are required, 1200 °C in a vacuum [36]:

$$3\,BaO + Si \rightarrow 2\,Ba + BaSiO_3$$

Either no reduction or only partial reduction combined with alloying occurs when barium oxide is treated with magnesium, calcium, sodium, or potassium. Barium can be isolated by reaction of barium iodide with sodium, whereas the chloride does not react. Electrolytic methods are not useful for industrial production and are only rarely useful for laboratory synthesis because of the solubility of barium in its molten halides [37]. It is unlikely that barium has ever been isolated in sufficient purity by electrolysis, even though this method has been mentioned numerous times [2].

1.4. Chemical Analysis

Volatile barium compounds impart a pale green color to flames, and this is an effective, simple qualitative test for barium (455.4, 493.4, 553.6, and 611.1 nm).

Barium is separated from magnesium, strontium, and calcium by precipitation from a dilute solution in nitric or hydrochloric acid with a solution of potassium dichromate in aqueous acetic acid. Barium is determined gravimetrically by precipitation of the sulfate [38]; small quantities are determined spectrometrically [39].

The metallic impurities in commercial barium (Table 3) are determined by atomic absorption and flame emission spectroscopy. Trace impurities are best determined by inductively coupled emission spectroscopy (ICP) [41]. The carbon content in barium is determined by combustion; nitrogen, by the Kjeldahl method; and hydrogen, by vacuum hot extraction. Vacuum hot

extraction is not useful for analysis of oxygen. Neutron activation analysis based on the reaction

$$^{16}\mathrm{O}\,(\mathrm{n,p}) \rightarrow {}^{16}\mathrm{N}$$

is the recommended method for determination of oxygen in alkaline-earth metals [42].

Table 3. Chemical analysis of commercial barium [40]

1.5. Transportation, Storage, Safety

Barium metal is commercially available in bars up to 20 kg or in rods 22 mm in diameter and 400 mm in length. The rods can be cut into small pieces or extruded into wires.

Barium is packaged in airtight steel drums containing up to 100 kg of the metal under argon or paraffin oil. Smaller amounts (1–10 kg) are packaged in tin cans, and even smaller samples are packaged in hermetically sealed glass bottles [43, 44].

Barium is a flammable solid and cannot be mailed. If it comes into contact with water, there is always the danger of explosion on account of the liberated hydrogen. Therefore barium should always be stored in a dry, well ventilated place and every contact with moisture and air avoided. Protective glasses and safety gloves should be worn while handling barium. Burning barium can be extinguished with sand, aluminum oxide, etc.

Transport classification [40]:

- GGVE, GGVS, RID, ADR: class 4.3, fig. 11b
- IMDG-Code: class 4.3 UN-No. 1400 PG.II
- ICAO: class 4.3 UN-No. 1400 PG.II/Drill-Code 4W

1.6. Uses

The main use of barium and barium – aluminum alloys is as *getter* to remove the last traces of unwanted gases from television picture tubes, transmitter valves, and other vacuum tubes [45 – 51]. Barium and its aluminum alloys also are used in incandescent lamps [52, 53]. Barium is particularly well suited as a getter because it has a low vapor pressure at the working temperatures of the tubes and is very reactive toward undesired gases, such as oxygen, nitrogen, hydrogen, carbon dioxide, water vapor, even removing residues of inert gases by inclusion.

Many other uses of barium have been described in the literature, but they are minor. For example, barium has been used in bearing alloys [54]; in lead – tin soldering alloys, where it increases creep resistance [55]; in nickel alloys for spark plugs [56]; in alloys with calcium, silicon, aluminum, and manganese that are used as deoxidizers for high-grade steel [20, 57]; and as an inoculant for steel and cast iron [58, 59]. Barium has also been used as a modifying agent for silumin, instead of strontium or sodium, because barium also refines the structure of the eutectic aluminum – silicon alloy [60]. Barium is also a good reducing agent; however, it is not normally used for this purpose because of its high atomic mass and its relatively high price, one kilogram of the metal costing about € 130 ($ 150) in 1998.

1.7. Economic Aspects

The leading producer, Chemetall GmbH, Germany, covers the global demand of Ba and $BaAl_4$. Nothing is known about production in the GUS and China, although facilities doubtlessly exist.

It is difficult to predict the future demand for barium. However, the replacement of television picture tubes by liquid crystal displays, or similar systems, is likely to decrease demand and production over the long term.

2. Barium Compounds

History. The first mention of barium compounds dates from the year 1602 when V. Cas-

CIOROLUS, in Bologna, realized that barite heated in the presence of organic substances phosphoresces in the dark. Much later, after 1774, C. W. SCHEELE discovered barium oxide and described its properties. He noted that a precipitate formed when sulfuric acid was added to barium oxide dissolved in water.

J. G. GAHN recognized that this was a reaction of the oxide to form barite, i.e., that the oxides were a new class of compounds. At that time the oxide was given the name baryta ($\beta\alpha\varrho\acute{\upsilon}\varsigma$ = heavy), which in some countries is still the name for technical grades: caustic baryta for the oxide, hydrate of baryta for the hydroxide. Today, however, the mineral heavy spar, $BaSO_4$, is meant by baryta or barite. Barium carbonate also occurs in nature. Native barium carbonate was named witherite, for W. WITHERING discovered the mineral in Cumberland, Great Britain, in 1783.

Raw Materials and Processing. The most important barium mineral is barite (barytes, heavy spar, barium sulfate, $BaSO_4$), today almost exclusively used as the raw material for the production of barium compounds. Barite occurs all over the earth in hydrothermal vein and sedimentary deposits. The main deposits of the mineral witherite ($BaCO_3$) are situated in England, Romania, and the USSR, but witherite is no longer of economic importance. No other mineral containing barium is used as a raw material for barium or its compounds at present.

The maximum world output of barite was $\approx 8.3 \times 10^6$ t (1981); however, only 7–8 % of this was used for the production of other barium compounds. Figure 1 shows how dressed barite is converted into other barium compounds. The barite is first reduced with carbon to give water-soluble barium sulfide, which is used mainly as an intermediate for the production of all other barium compounds and lithopone [61 – 65].

Chemical Analysis. All barium compounds may be identified by the green color imparted to flames. For quantitative analysis, atomic absorption spectroscopy (AAS), flame emission spectroscopy (OES-ICP), X-ray spectroscopy, complexometry, ion chromatography (IC), and gravimetry are suitable. (For chemical analysis of barium metal see Section 1.4.)

Economic Aspects [66, 67]**.** Production data is available only for barium sulfate, the most important barium compound and the starting material for the production of most other barium compounds. The worldwide barite production has continued to increase from about 5.3 $\times 10^6$ t in 1996 to 5.8×10^6 t in 2000, 6.5×10^6 t in 2003, 7.3×10^6 t in 2004 up to about 7.6×10^6 t in 2005. Since the 1990s, China has been the main producer of barites and is continuing to strengthen its position. Its share of the market has increased from 30 % in 1990 to more than 50 % in 2005. Other significant producers are India (14 %) and the USA (7 %), followed by Marocco (4 %), Mexico (4 %), and Iran (3 %). Barite production primarily reflects worldwide crude oil and natural gas exploration, since at least about 80 % of its production is used in drilling fluids for these industries. A large portion of this type of barites is used in the oil industry of the Golf of Mexico. Consumption and the source of barites is mostly dominated by freight costs. In the Golf of Mexico, for example, most of the barites is imported from China in the form of lumps that are then processed in grinding mills at various locations on the Golf coast. American sources, mostly from Nevada, are primarily used in Canada and the western and north-western parts of the USA. Indian barite is most competitive in the Middle East and in local markets. Due to the increasing oil demand and the phasing out of Chinese VAT rebates, the prices for barites have continued to rise. Increasing freight rates due to globalization of the markets have assisted in this development. Depending upon the price of the barites, haematite may be a possible replacement, depending upon freight rates. As of today, awareness for environmental issues is growing, such as the mercury contents of the barites used.

The other important uses of barite are as a starting material for the production of barium compounds (see Fig. 1) and its direct use in bleached or unbleached form as a filler in paints and plastics. Consumption of barite in drilling muds varies considerably, while the other two markets are less subject to change. Therefore, it is difficult to obtain reliable relative percentage data. An estimated balance for 1995 is 76–80 % for oil development, 9–13 % for industrial use, and 5–9 % for direct use as a filler.

Figure 1. Production pathways to various barium compounds starting from barite

Identified barite reserves amount to 170×10^6 t with prospects for a total of 500×10^6 t worldwide.

2.1. Barium Sulfate

Barium sulfate is the most important barium compound, and the mineral barite, $BaSO_4$, also called heavy spar or barytes, is by far the most important barium mineral.

2.1.1. Properties

Barium sulfate [*13462-86-7*], $BaSO_4$, M_r 233.39. The industrially precipitated product is called blanc fixe [*7727-43-7*], which is French for "permanent white". Pure $BaSO_4$ forms colorless rhombic crystals of refractive index $\approx$ 1.64, hardness 3–3.5 (Mohs scale), and density ϱ 4.48 g/cm^3. Heating $BaSO_4$ decomposes it, the rate increasing with temperature over the range 1100–1500 °C. The main products are BaO, SO_2, and O_2. For this reason melting points given in the older literature — 1345 °C or 1580 °C — differ. Barium sulfate is almost insoluble in water, the solubility being 2.5×10^{-4} wt % at 20 °C and 3.9×10^{-4} wt % at 100 °C. The solubility of barium sulfate is enhanced by the presence of chelating compounds. For example, it is dissolved by aqueous ethylenediamine tetraacetic acid (EDTA). Barium sulfate is more soluble in hot concentrated sulfuric acid and in melts of alkali-metal salts. The most important reaction of barite is its reduction with carbon to produce barium sulfide.

2.1.2. Barite

In nature, barite [*13462-86-7*] rarely occurs as a pure white mineral; generally, its color is yellowish, pink, reddish brown, dark gray, or black.

The main impurities are quartz, calcium carbonate, iron and manganese oxides, fluorite, strontium sulfate, pyrite, lead glance, zinc blende, and sometimes bituminous substances, the impurities and their amounts depending on the particular deposit. To remove these impurities before the barium sulfate is used industrially, in most cases barite is given a preliminary treatment to increase the $BaSO_4$ content to 90–97 wt %.

Deposits. Barite deposits are found in all regions of the world. The most important sources in Europe are in Germany, France, Italy, the UK, Belgium, and Spain, with minor amounts coming from Portugal and Greece. Kasakhstan, Bulgaria, Romania, and, to a lesser extent, Georgia, Slovakia, and Poland supply the Central and Eastern European markets.

In the Americas, significant deposits are found in the United States, Canada, Mexico, Brazil, and Argentina.

Morocco is the most important producer in Africa, followed by Algeria and Tunesia.

The largest producer of barite is China (appr. 3.8×10^6 t/a). Other major barite producers in the middle and Far East are India, Iran, and Turkey, with further amounts coming from Indonesia, North Korea, and Thailand, and lesser amounts from Pakistan, Malaysia, Japan, and Australia.

Mining and Dressing of the Ore. Barite is usually mined in open cuts, only sometimes in open pits or underground galleries. The ore is washed in trommels to remove adherent argillaceous impurities, then crushed in breakers, and classified. The various grain sizes are liberated from the mostly quartz gangue in jigs, thus enriching the barium sulfate. This wet mechanical dressing is adequate for many uses. If there is a high degree of intergrowth of quartz and barite and if the ore contains much iron, lead, or zinc, flotation is required. This produces 98 wt % $BaSO_4$ [69]. Sometimes barite is a by-product of the flotation of pyritiferous ores. The flotation agents and the pH depend, among other things, on the impurities present in the crude ore [70]. Generally the barite is wet ground to a grain size of 0.1 mm before flotation. Sodium oleate, tall oil, oleic acid, and alkyl sulfonates and sulfates have been used as collectors. Water glass is the preferred depressant, especially for quartz and iron oxides. Flotation processes to depress the $BaSO_4$ and float the impurities are confined to a few special cases, e.g., ore rich in fluorite [71].

Another method applicable only to special barite types is based on the tendency of these barites to decrepitate. The broken ore is heated to ≈ 700 °C in rotary kilns, the barite crystals bursting while the gangue is unaffected. The decrepitated fines rich in barite are screened off from the gangue. The yield depends above all else on the suitability of the barite for this treatment.

Barite grades with special properties are produced for the various industrial uses.

Drilling Muds. About 80 % of the world output of barite is ground and used to increase the density of drilling muds, especially for drilling oil and gas wells. The muds consist of an aqueous clay suspension and additives. The large amount of barite that can be added to this suspension allows adjustment of the density to a high value without the viscosity being affected significantly. The increased density allows faster discharge of cuttings and prevents blowouts. The standards for drilling-mud-grade barite vary from country to country; however, the OCMA or API standards widely accepted [72]. These regulate the viscosities of aqueous suspensions, the density of the barite (related to the barium sulfate content), its particle size distribution, and the content of water-soluble materials. Higher contents of water-soluble materials, especially divalent cations such as calcium, can cause flocculation of the clay components of drilling muds [73].

For the production of barite for drilling muds, generally it is sufficient to jig the ore to increase the density by removing the quartz. In most cases the other impurities do not cause trouble. On the other hand, barite that has been floated must be heated or treated in some other way to destroy its hydrophobic character.

Raw Material for Barium Chemicals. The 7–8 % of the total barite production used as a raw material for other barium compounds is always reduced to barium sulfide as the first stage. The $BaSO_4$ content must be $\geqq 95$ wt %, and the $BaSO_4$ should contain as little silica and iron as possible, as these impurities reduce the

yield of water-soluble barium sulfide [*21109-95-5*]. Fluorspar (fluorite) and lead glance interfere with the reduction. Such barite is generally shipped in bulk as coarsely broken material, either granular (jigged) or ground (floated).

Mined Barites [66]**.** Mined barites may be separated into "white" and "off-white" grades. The whiteness of a barite is a measure for its purity. Off-white grades are used as a source for barium chemicals and directly as off-white fillers.

Off-white Barite Filler. The use of off-white barites is more or less limited to sound-deadening applications and to dark formulations, such as automobile underbody sealants. The sound-deadening action is related to the high density of barium sulfate.

White Ground Barite Filler. Ground barite is used as a filler owing to its resistance to chemicals and weathering, its wettability and dispersibility, and its low adsorption of binders. The properties of barite flour vary, depending on the commercial grade:

Grain size	0.1–40 µm
Brightness (reference, $BaSO_4$ white standard = 100)	85–95
Refractive index n_D	$\approx$ 1.64
Oil requirement	10–12 g of oil/100 g
Bulk density, tamped	1.4–2.2 g/cm^3
Density	4.0–4.25 g/cm^3

Some white barite grades may be ground directly without further treatment. More usual, however, is to subject the spar to coarse crushing and gravity dressing. Then the granular material is treated in bleaching vats with hot dilute acid, preferably sulfuric or hydrochloric acid, to remove the colored iron or manganese oxides, washed, and dried. The bleached spar is dry-milled in edge or ball mills to obtain the desired grain size, then air classified.

There is a more economical procedure: the coarsely crushed, gravity dressed barite is ground to the desired grain size by continuous wet milling in lined ceramic tubes. The screened suspension of ground material is bleached in agitator vessels, with dilute sulfuric or hydrochloric acid along with reducing agents (e.g., sodium sulfite) or oxidizing agents (e.g., nitric acid), depending on the kind of impurities, then washed, decanted, and dried. If floated barite is used in this process, then the barite must be floated again after bleaching to remove the decomposed organic material [74].

A third bleaching procedure lacks economic importance: here the barite is heated in a rotary kiln by adding alkali-metal salts, e.g., sodium chloride or sodium hydrogensulfate. This procedure is confined to special cases due to its high cost.

The specifications for ground barite are given in DIN 55911 for the Federal Republic of Germany and ISO 3262 internationally. The requirements of the buyers differ in regard to grain size and whiteness. Some products, such as EWO-Albaryt grades of the Deutsche Baryt-Industrie, Bad Lauterberg/Harz, are equivalent to synthetic blanc fixe in many respects. White ground barite is generally shipped in 25 or 50 kg paper bags, 1000 kg big bags, or in silo trucks.

Barite flours are mainly used as fillers and extenders in paints, varnishes, plastics, rubber, linoleum, sealing compounds, stoppers, plasters, and adhesives (5–9 % of the total barite production). High-quality grades can be used as an X-ray-opaque medium in medicine, provided they meet the requirements of the individual countries as given in USP, EP, JP, DAB, etc.

2.1.3. Blanc Fixe

Precipitated barium sulfate is usually called blanc fixe [*7727-43-7*]. It is mainly used as a filler and extender, in some fields also as a white pigment. The most important properties for the consumer are its insolubility in water and organic binders, its high degree of whiteness, and its homogeneous granulation:

Grain size	0.1–20 µm
Average grain size	0.2–4 µm
Brightness (reference, $BaSO_4$ white standard = 100)	95–99
Refractive index n_D	$\approx$ 1.65
Oil requirement	12–22 g of oil/100 g
Bulk density, tamped	0.9–2.2 g/cm^3
Density	4.0–4.4 g/cm^3

Certified ultrahigh-purity blanc fixe, which must also fulfill certain handling requirements, is used as a white standard in UV – Vis spectroscopy instead of magnesium oxide, which is no longer user for this purpose.

Production. Blanc fixe is usually precipitated in stirred tanks from solutions of barium chloride or barium sulfide by adding dilute sulfuric acid or sodium sulfate solutions. The sulfuric acid or the sodium sulfate solution must be free from heavy metals that can impart color to the product.

The method of manufacture and the reaction conditions depend on the ultimate use of the blanc fixe, especially the desired grain size. For example, fine-grained blanc fixe is produced by rapid precipitation from highly concentrated solutions at high pH and low temperatures. Coarse blanc fixe is produced from dilute solutions at high temperatures, say 80–100 °C. The use of seed crystals and prolonged residence time, e.g., by stirring for an extended period at low pH, produces a larger average grain size in the finished product. The precipitated blanc fixe is filtered or centrifuged and washed. It is drawn off and packed as paste, slurry, or powder, the last involving an additional process step of drying and perhaps one of regrinding.

A special problem in preparing blanc fixe from barium sulfide and sodium sulfate solutions is washing out the sodium sulfide. However, this problem can be overcome by enlarging the particle size of the extremely fine material by sintering (at 300–1000 °C) with fluxes like sodium sulfate and extracting the clinker [75].

Another procedure for the manufacture of blanc fixe is based on the conversion of an aqueous suspension of barium carbonate with dilute sulfuric acid, sometimes in the presence of small amounts of hydrochloric acid. The resulting product is characterized by its whiteness [76].

Formerly blanc fixe was obtained as a byproduct of hydrogen peroxide production by reaction of barium peroxide and sulfuric acid, but today hydrogen peroxide is prepared by the anthraquinone process (see → Hydrogen Peroxide).

Quality Specifications. In the Federal Republic of Germany, the standards for blanc fixe, the methods of analysis, and tests are defined in DIN 55 911. The various grades differ mainly in grain size. The smaller the grain diameter the higher the luster. In fact, grades are still sometimes characterized as mat, semimat, or lustrous.

The standards for blanc fixe to be used as X-ray-opaque medium in medicine are described and defined for the various countries in USP, EP, JP, DAB, etc. The standards deviate slightly from one to another.

Shipping and Packing. Blanc fixe is shipped as powder (usually in 25 kg paper bags, big bags, or in silo trucks); slurry (30–40 % water in tank trucks); and agglomerate-free paste (25–35 % water in 50 kg polyethylene-lined sacks). Because blanc fixe is nontoxic, it is not classified as a dangerous good.

Uses. About 70 % of the blanc fixe consumed in Western Europe is used in paint and varnish as well as in printing ink as a filler. It is used as a coating pigment to upgrade the surface of paper and is sometimes used as a pulp filler. Photographic paper requires grades free from sulfur and heavy metals, but this market has lost significance. Today, anatase-grade TiO_2 is used instead. Blanc fixe is also used as a filler in plastics, rubber, and adhesives and as an additive in the negative plates of lead storage batteries. Special grades are used as a medium opaque to X-rays for medical purposes (stomach X-rays).

Nanoscaled barium sulfates have proven useful in improving mechanical properties of certain polymers such as epoxy systems. Similar to nanoscaled titanium dioxides, they are able to improve the hardness as well as the fracture toughness of these polymers [77]. Because of the low refractive index of barium sulfate, it is possible to formulate clear coats with a high transparency even with large amounts of the nanoparticles. These films have an enhanced resistance to chemicals and improved scratch resistance.

2.2. Barium Sulfide and Polysulfides

The principal intermediate between barium sulfate and other barium compounds is barium sulfide.

Properties. Pure barium sulfide [*21109-95-5*], BaS, M_r 169.40, ϱ 4.3 g/cm^3, forms colorless cubic crystals. It melts above 1200 °C. Its heat capacity c_p is 287 J kg^{-1} K^{-1}. At room temperature barium sulfide is unaffected by dry air, but over the range 500–1000 °C it is oxidized to barium sulfate, at an ever-increasing rate. In humid

air containing carbon dioxide, some barium carbonate forms, and the odor of hydrogen sulfide is noticeable. The solubility of barium sulfide in water depends strongly on the temperature, the maximum being near 90 °C:

°C	0	20	40	60	80	90	100
wt % BaS	2.8	7.3	13.0	21.7	33.3	40.2	37.6

Owing to complete hydrolysis, a solution of sulfide is actually an equimolar solution of barium hydroxide [*17194-00-2*], $Ba(OH)_2$, and barium hydrosulfide [*25417-81-6*], $Ba(SH)_2$. Accordingly, barium sulfide does not precipitate when the solution is cooled; instead, a double salt of composition $Ba(OH)_2 \cdot Ba(SH)_2 \cdot 10\ H_2O$ [*42821-46-5*] precipitates. Excess hydrogen sulfide converts the barium hydroxide in solution quantitatively to barium hydrosulfide, which can be precipitated as $Ba(SH)_2 \cdot 4\ H_2O$ [*12230-74-9*] by addition of ethyl alcohol.

Aqueous barium sulfide reacts with carbon dioxide to form barium carbonate [*513-77-9*], $BaCO_3$, and the solution is also susceptible to atmospheric oxygen, which easily oxidizes the hydrosulfide to polysulfide, thiosulfate, and sulfite.

Production. Barium sulfide is produced by reducing barite ($BaSO_4$) with carbon. The net reaction is

$$BaSO_4 + 2\ C \rightarrow BaS + 2\ CO_2$$

However, the thermodynamic data suggest that the actual reducing agent is carbon monoxide [78]:

$$BaSO_4 + 4\ CO \rightarrow BaS + 4\ CO_2$$

Barium sulfite, $BaSO_3$, is an intermediate [79]. The CO forms in the reaction between carbon and CO_2, the Boudouard equilibrium:

$$C + CO_2 \rightleftharpoons 2\ CO$$

The barite should have a $BaSO_4$ content $\geqq 95$ wt %. Large amounts of impurities, especially silica and iron oxide, reduce the yield of water-soluble barium sulfide by forming the insoluble barium silicates and ferrates. The spar is ground to 0.1–2 mm and mixed with low-ash reducing carbon or coke, one part of carbon to 4–6 parts of barite.

Today the reduction is usually carried out in a continuous process centered around rotary kilns up to 50 m long. A burner at the outlet of the kiln fired with fuel oil, natural gas, or coal dust provides countercurrent heating. Reduction takes place at 900–1200 °C; average residence time is 90–120 min. The operating conditions must be carefully controlled to prevent secondary reactions with the gangue and to impede caking. The barium sulfide melt should be obtained in a fine-grained condition. The sulfide melt leaves the kiln continuously through a cooling drum. Generally further grinding is not necessary.

Various processes using a fluidized-bed kiln have been reported. Here, the pulverized spar, e.g., from flotation, is granulated together with carbon and reacted in a fluidized bed, a part of the carbon being used for heat generation and a part for reduction [79, 80]. Other processes use a reducing gas, e.g., carbon monoxide or methane, instead of carbon. The gas serves three functions: it provides heat upon combustion, it supports the fluidization, and it is the reducing agent. The advantages are a reduction temperature below 1000 °C, a residence time less than 1 h, and a more favorable energy balance [81, 82]. However, large-scale plants of this kind have not been reported.

Crude barium sulfide (black ash) is *leached* countercurrently with 60–80 °C water to dissolve the barium sulfide. This leaching is carried out batchwise in batteries of Shank leaching vats or continuously in closed agitated vessels followed by several thickeners. The suspended matter is filtered off, and the lye, containing 13–18 % BaS, is immediately treated further to prevent oxidation or crystallization. At this point the barium sulfide solution is very pure.

The residue still contains 50 % barium, in the form of compounds insoluble in water, such as silicates and ferrates of barium and unreacted barite. The silicates and ferrates can be dissolved with hydrochloric acid to form barium chloride; however, this process is often uneconomical because of the cost of purifying the barium chloride solution. To avoid these problems it has been proposed that the leaching residue be resuspended in water and, by adding hydrogen sulfide, the portion of barium compounds that are insoluble in water be converted into readily soluble barium hydrosulfide that can be led back into the sulfide lye [83].

Quality Specifications. Barium sulfide is available only as a technical-grade, granular, dark gray crude product called black ash. It contains 75–85 % water-soluble BaS, barium compounds soluble in hydrochloric acid (8–10 % as BaO), 2–4 % SiO_2, 2–3 % Fe_2O_3 and Al_2O_3, 2–4 % $BaSO_4$, and 1–2 % carbon. The economic value depends directly on the content of water-soluble BaS, which is determined analytically by acidimetry and iodometry.

Packing and Shipping. Barium sulfide is packed in 25 kg paper bags with an inner polyethylene bag. Shipment is governed by IMDG Class 6.1, UN 1564, and RID/ADR Class 6.1, 60c.

Uses. Barium sulfide is mainly used for the production of other barium compounds, especially blanc fixe and lithopone. Some BaS is used for the production of hydrogen sulfide; in this case, barium chloride is the byproduct. Other uses (depilatories, purification of mineral acids) are far less important.

Barium Polysulfides. The polysulfides [*50864-67-0*] have the general composition BaS_x (x = 2–5). They include barium disulfide [*12230-99-8*], BaS_2; barium trisulfide [*12231-01-5*], BaS_3; barium tetrasulfide [*12009-34-6*], BaS_4; barium tetrasulfide monohydrate [*12448-67-8*], $BaS_4 \cdot H_2O$; barium tetrasulfide dihydrate [*12231-03-7*], $BaS_4 \cdot 2\,H_2O$; and barium pentasulfide [*12448-68-9*], BaS_5. Polysulfides form when barium sulfide solutions are oxidized by air, when sulfur is dissolved in barium sulfide solutions, when barium sulfide is fused with sulfur in a vacuum, etc.

The isolation of individual polysulfides from solution is difficult because of their tendency to decompose. Technical barium polysulfide can also be produced by grinding barium sulfide with sulfur (Ba : S = 1 : 4–5). It is marketed as a grayish-yellow powder. The formation of polysulfide does not take place until the powder is dissolved.

One process, however, produces a mixture of true barium polysulfides, BaS_{4-5}, by sudden evaporation of a solution in a spray dryer [84]. The resulting light yellow powder is stable and dissolves in water without leaving a residue.

As a 1–3 % solution, barium polysulfide is a fungicidal and acaricidal agent used in fruit and grape growing.

Shipment of barium polysulfides is governed by the IMDG Class 6.1, UN 1564, or RID/ADR Class 6.1, 60c.

2.3. Barium Carbonate

Barium carbonate is the most important manufactured barium compound after blanc fixe. It occurs in nature as witherite, which has little economic significance due to rareness, inevitable impurities, and almost fully depleted deposits.

Properties. Barium carbonate [*513-77-9*], $BaCO_3$, M_r 197.35, *mp* 1360 °C accompanied by loss of CO_2. Pure barium carbonate is a white fine crystalline powder having several modifications:

$$\gamma\text{, rhombic} \xrightleftharpoons{803\,^\circ\mathrm{C}} \beta\text{, hexagonal} \xrightleftharpoons{980\,^\circ\mathrm{C}} \alpha\text{, cubic}$$

The rhombic modification is isomorphous with the carbonates of calcium (aragonite), strontium (strontianite), and lead (cerussite).

Barium carbonate has a density of 4.29 g/cm^3. Its solubility in water at 20 °C is only 2 $\times 10^{-3}$ wt %, although it is a little more soluble in water containing CO_2. Its refractive index is $\approx$ 1.6. Its heat capacity c_p at room temperature is 433 J kg^{-1} K^{-1}.

When barium carbonate is heated, it loses carbon dioxide and forms barium oxide. The dissociation is promoted by traces of water. Barium carbonate and its decomposition product barium oxide are partially soluble in each other at elevated temperatures, at 1000 °C $\approx$ 10 mol % oxide in the carbonate and $\approx$ 5 mol % of carbonate in the oxide — this partial solubility was not adequately appreciated in the older literature. Moreover, there is a eutectic at 1060 °C with 34 mol % barium oxide. The equilibrium CO_2 pressure above barium carbonate saturated with oxide increases rapidly above 1000 °C [85, 86]:

°C	900	1000	1100	1200	1250	1300	1360
kPa	0	0.21	1.6	10.1	21.6	46.4	101.3
Torr	0	1.6	12	76	162	348	760

Production. Barium carbonate is produced almost exclusively by precipitation from barium sulfide solutions. There are two processes:

1) precipitation with carbon dioxide
2) precipitation with soda

The first is based on the reactions

$$2\,BaS + CO_2 + H_2O \rightarrow BaCO_3 + Ba(HS)_2$$

$$Ba(HS)_2 + CO_2 + H_2O \rightarrow BaCO_3 + 2\,H_2S$$

The carbon dioxide is usually available from combustion gases or native carbonic acid. The precipitation is carried out batchwise in gastight vessels, several of which may be arranged in series to absorb the carbon dioxide that breaks through with the hydrogen sulfide in fresh lye; a utilizable hydrogen sulfide poor in carbon dioxide is produced in this way. Also there are continuous processes, e.g., using precipitation columns [87, 88].

The second process is based on the reaction

$$BaS + Na_2CO_3 \rightarrow BaCO_3 + Na_2S$$

The barium sulfide lye containing 15–18 wt % BaS is run into ≈ 30 wt % soda solution in agitator vessels.

The decision to favor one or the other of the two processes does not depend only on the availability and relative cost of carbon dioxide or soda. Above all else the value or sales prospects of the byproducts, H_2S or Na_2S, is decisive. The hydrogen sulfide must be worked up to sulfur, sulfuric acid, sodium hydrosulfide, or sodium sulfide. The dilute sodium sulfide solution produced in the soda process in most cases is upgraded to crystalline sodium sulfide hydrate (60 wt % Na_2S).

The main impurity in $BaCO_3$, sulfur as sulfide, elemental sulfur, or sulfate, is the major problem. Patents offer a number of solutions: adding aluminum powder to the barium sulfide lye to reduce the polysulfide sulfur [89]; continuously maintaining a residual barium sulfide content in the solution of ≈ 0.5 wt % during the precipitation with carbon dioxide to keep the sulfur dissolved [90]; or a careful step-by-step precipitation, perhaps first to $BaCO_3$ and $Ba(HS)_2$ and then to $BaCO_3$ and H_2S [87, 88].

Quality Specifications. Purity, bulk density, and grain-size distribution depend on the particular use. Usually, low sulfur and heavy-metal content is demanded. The manufacturers of electroceramics require low strontium content. The numbers below refer to products of various origin, quality, and process and should only be regarded as reference values:

Barium carbonate	≧ 98.5 %
Sulfur	0.08 (0.02) %
Strontium	0.5–1.4 (0.3) %
Iron	$6–20 \times 10^{-4}$ %
Insoluble in $HCl_{(soln)}$	0.1–0.6 %
Density	4.29 g/cm^3
Bulk density, tamped	0.4–1.8 (2.2) g/cm^3
Grain size, < 5 µm	80–95 %

An important standard for barium carbonate as a sulfate-binding agent is its reactivity. This is determined by conversion of barium carbonate with known quantities of sulfate, as gypsum water or sodium sulfate solution.

Packing and Shipping. Barium carbonate is stored in silos and shipped in multilayer paper bags, big bags, or silo wagons. Shipment is governed by the IMDG Class 6.1, UN 1564, or RID/ADR Class 6.1, 60c.

Uses. Barium carbonate is used to remove the detrimental sulfate ion from the input solutions of the chlor-alkali electrolysis, e.g., the mercury process, as well as from industrial waters of various kinds. In brick production, barium carbonate is a binder for the soluble sulfates in the raw mixture. The formation of insoluble barium sulfate prevents discoloration (efflorescence) during production. Moreover, barium carbonate reduces the tendency of baked bodies to effloresce on exposure to moisture. Barium carbonate is used to incorporate barium oxide into special fine glassware, apparatus glass, and many optical glasses. The barium oxide increases the workability of the glass melt, improves the mechanical and chemical resistance, and increases the density and refractive index of the glass.

Barium in television screens prevents the leakage of X rays. In the western world, the demand for cathode ray tube (CRT) televisions is declining since LCD (liquid crystal displays) and plasma screens are increasingly being used. As CRT televisions are, however, much cheaper,

they are still favored in India and China, where most CRT production is still based.

Barium carbonate is also used in enamels and for the production of the electroceramic barium titanate [*12047-27-7*] and the magnetoceramic barium ferrites [*12047-11-9*]. These last two uses require high-purity $BaCO_3$. Barium carbonate is also used in the synthesis of high-temperature superconductors.

2.4. Barium Chlorate

Barium chlorate monohydrate [*10294-38-9*], $Ba(ClO_3)_2 \cdot H_2O$, M_r 322.26, forms monoclinic short prismatic crystals of density 3.18 g/cm^3. Its solubility in water is 21.2 wt % at 10 °C and 51.3 wt % at 100 °C. Near 120 °C barium chlorate begins to lose its water of crystallization, and above 250 °C oxygen is lost. The anhydrous salt melts at 415 °C; however, explosions can occur on fusion or if a mixture with sulfur or organic substances is heated even at 110 °C. Barium chlorate is a good oxidant.

Barium chlorate is produced on an industrial scale by mixing concentrated barium chloride solution into hot concentrated sodium chlorate solution. On cooling, barium chlorate monohydrate crystallizes. Although it crystallizes in a rather pure form, barium chlorate can be purified even further by recrystallization. This double conversion is more economical than electrolysis of a barium chloride solution, a process that is no longer used.

Barium chlorate is almost exclusively used in pyrotechnics, where it produces a green color. In addition, it has been used as an oxidizing agent, e.g., in textile printing. Shipment is governed by IMDG Class 5.1, UN 1445, or RID/ADR, Class 5.1, 29b.

2.5. Barium Chloride

Anhydrous barium chloride [*10361-37-2*], $BaCl_2$, M_r 208.25, *mp* 962 °C, ϱ_{20} 3.91 g/cm^3, crystallizes in two modifications: α-$BaCl_2$ (rhombic, mostly lamelliform) and β-$BaCl_2$ (cubic). The conversion temperature is 925 °C. Barium chloride is soluble in water:

°C	0	20	40	60	80	100
wt % $BaCl_2$	23.6	26.3	29.0	31.6	35.0	36.6

The enthalpy of fusion is 193 kJ/kg, and the entropy of fusion is 87.7 J kg^{-1} K^{-1}. The heat capacity c_p is 361.8 J kg^{-1} K^{-1} near room temperature.

Barium chloride crystallizes from aqueous solutions as the dihydrate [*10326-27-9*], M_r 244.31, in monoclinic colorless plates, ϱ 3.097 g/cm^3. Water of crystallization is not lost much before 110 °C, this process being finished around 160 °C.

Production. Today the production of barium chloride on an industrial scale is carried out by the reaction of 15–18 wt % barium sulfide solution with 31–32 wt % hydrochloric acid. In addition, the reaction of barium sulfide solution with chlorine is of commercial interest.

In both methods, reaction is continued until the solution becomes acidic to assure complete conversion of the barium sulfide and to remove from solution the hydrogen sulfide formed. The reaction with hydrochloric acid is often followed by oxidation with air or chlorine to convert any dissolved sulfur compounds into barium sulfate, which removes the sulfur from the solution. In both methods, the solution is neutralized afterwards with barium carbonate or sodium hydroxide to precipitate heavy metals.

The solubility of $BaCl_2$ in water does not depend strongly on temperature. If the barium chloride is to be crystallized, this is carried out by evaporative crystallization. In most cases, vacuum evaporation is used, the salt crystallizing as the dihydrate. Normally it is only dried but it can be dehydrated further if necessary. The mother lye, which still contains barium chloride, can be processed to produce insoluble blanc fixe ($BaSO_4$) or barium carbonate. The byproduct hydrogen sulfide from the hydrochloric acid process can be converted into sodium sulfide or sodium bisulfide or oxidized to produce sulfuric acid.

In the chlorine process, the byproduct is sulfur, usually containing barium carbonate and heavy metals.

Byproduct barium chloride is obtained in the production of lithopone grades containing more than 30 wt % zinc sulfide, for in these cases barium sulfide is reacted with zinc sulfate and zinc chloride. Another source of barium chloride is the black ash leaching residues. These are reacted with hydrochloric acid by some manufac-

turers. However, the resulting barium chloride solutions contain such a concentration of impurities that they must be purified extensively before further use.

The literature reports various procedures to convert barite directly into barium chloride. These procedures, e.g., the reaction of barite with carbon and calcium chloride or the chloridizing reduction of barite, no longer have significance in Western Europe or America, for they are now uneconomical. Direct conversion may still be of interest in Eastern Europe, where numerous scientific papers and patents on direct conversion have been issued, e.g., [91]. The industrial production of barium chloride from barium sulfate, carbon, and calcium chloride is reported only from the People's Republic of China.

Quality Specifications, Packing, Shipping. Both the dihydrate and anhydrous barium chloride are marketed as technical grades of 99–99.5 %, the dihydrate also being available as a high-purity grade (≈ 100 %). They are packed in 50 kg multilayer paper bags with polyethylene covers or liners to protect against moisture. Shipment is governed by IMDG Class 6.1, UN 1564 (harmful, keep separate from foodstuffs), or RID/ADR Class 6.1, 60c.

Uses. Along with other chlorides, barium chloride is used as a component of melt quenching baths for steel. It is used as a starting material for the production of sulfide-free blanc fixe grades and, instead of barium carbonate, to remove sulfate from solutions. Finally, it has a limited importance as a stabilizer for plastics.

2.6. Barium Ferrite

Barium hexaferrite [*12047-11-9*], $BaFe_{12}O_{19}$, M_r 1111.49, forms hexagonal needle-shaped ferrimagnetic crystals. It is usually manufactured in a two-stage solid-state reaction, first stage at 650–750 °C, second stage > 850 °C. An intermediate is barium monoferrite [*12009-00-6*], $BaFe_2O_4$ (→ Magnetic Materials).

2.7. Barium Oxide

Barium oxide [*1304-28-5*], caustic baryta (an older term), BaO, M_r 153.33, *mp* ≈ 1920 °C, sublimes ≈ 2000 °C. Pure commercial barium oxide is a white fine crystalline powder, whereas technical grades are often gray due to carbon impurities. Barium oxide forms face-centered cubic crystals. The densities reported in the literature vary considerably, perhaps depending on preparation. The most likely value is ≈ 5.7 g/cm^3.

Usually barium oxide is very reactive. However, its reactivity depends on the preparative conditions, the reaction temperature, and the coreactant. In the absence of water, BaO often reacts very slowly with carbon dioxide. In the presence of small amounts of water, however, it is converted by carbon dioxide into barium carbonate in a very exothermic reaction. The conversion of barium oxide by water into barium hydroxide is also very exothermic. Self-ignition may occur on contact with wet organic substances. Barium oxide is soluble in methanol: 20 wt % dissolves at 15 °C, and therefore barium oxide can be purified by recrystallization before it is used as a starting material for organic barium compounds or for incorporation, as a methylate, into organic systems.

Production. Barium oxide is mainly produced by decomposition of barium carbonate in the presence of carbonaceous material at high temperature. The use of carbon significantly lowers the temperature at which the barium carbonate decomposes, which to a large extent avoids unwanted corrosion of the reactor when barium carbonate is decomposed by heat alone at 1400 °C. Also important is the decomposition of barium carbonate mixed with channel black (6.2 wt % C) in retorts of silicon carbide – corundum externally heated to ≈ 1250 °C.

The modern procedures tend to use continuous fluidized beds. Barium carbonate – soot pellets are used [92, 93], or the carbon is added to the fluidized bed as methane [94]. The advantages are, among others, that the low reaction temperatures give less-sintered products, i.e., more reactive BaO.

There are also procedures using electrical arcs in a core zone [95]. In such processes a steep temperature drop is maintained between the hot core zone and the reactor shell, to provide a protective layer for the shell material. Addition of carbon is not absolutely necessary.

The crude barium oxide can be reacted [93, 94] in a second stage with carbon for more complete conversion.

Quality Specifications. Barium oxide is marketed in grades of a purity of 97–99 wt %. The main impurities are 1–3 wt % barium carbonate, $\leqq$ 1 wt % barium peroxide, and a few tenths of a percent of nonconverted carbon.

Storage and Shipping. Barium oxide is shipped mainly in iron drums or, for smaller quantities, in tin cans. Shipment is governed by the regulations on the transport of harmful goods of the IMDG Class 6.1, UN 1884, or RID/ADR Class 6.1, 60c.

Uses. Barium oxide, like barium hydroxide, is mainly used for the preparation of additives for oils and greases; however, this is losing significance. In addition, barium oxide is used as a starting material for organic barium salts used in plastics. Barium oxide is frequently used in the production of luminescent materials.

2.8. Barium Peroxide

Barium peroxide [*1304-29-6*], BaO_2, M_r 169.33, → Peroxo Compounds, Inorganic, Section 2.1.2.

2.9. Barium Hydroxide

The anhydrous hydroxide has only a secondary industrial importance; the monohydrate and octahydrate are used in industry on a far larger scale.

Properties. Barium hydroxide octahydrate [*12230-71-6*], hydrate of baryta, caustic baryta, $Ba(OH)_2 \cdot 8\ H_2O$, M_r 315.47, forms monoclinic pseudotetragonal crystals, often plates when rapidly crystallized. It dissolves at 78 °C in its own water of crystallization, releasing the water when heated above 108 °C to yield the monohydrate. The enthalpy of melting is high at a value of 280 J / g. The density is ≈ 2.18 g/cm^3. The specific heat capacity c_p of the solid is 1250 J kg^{-1} K^{-1}, of the melt 1675 J kg^{-1} K^{-1} at 80 °C.

The solubility in water depends dramatically on the temperature:

°C	0	20	40	60	78
wt % $Ba(OH)_2 \cdot 8\ H_2O$	3.0	6.9	14.1	32.6	100.0
g BaO/100 g H_2O	1.5	3.48	7.35	18.8	94.7

The solutions are strongly alkaline and tend to supersaturate.

Like all soluble hydroxides, barium hydroxide, especially in aqueous solution, reacts readily with acidic gases. The most important example in practice is carbon dioxide, to form barium carbonate.

Barium hydroxide monohydrate [*22326-55-2*], $Ba(OH)_2 \cdot H_2O$, M_r 189.37, crystallizes as often radially intergrown needles. Its density ϱ_{20} is ≈ 3.74 g/cm^3. The monohydrate does not react with dry carbon dioxide.

Anhydrous barium hydroxide [*17194-00-2*], $Ba(OH)_2$, M_r 171.35, *mp* ≈ 407 °C. The course of the dehydration, i.e., the temperatures and times, from monohydrate to anhydrous $Ba(OH)_2$ depends on the reactivity of the monohydrate. Molten anhydrous hydroxide is so corrosive, attacking steel and most ceramics, that the conversion of barium hydroxide into barium oxide, which takes place at 800 to 850 °C, is not carried out on an industrial scale.

Production. Barium hydroxide octahydrate can be produced by hydration of barium oxide. The barium oxide is suspended in recycled mother liquor and heated for several hours to destroy peroxides. The insolubles, e.g., $BaCO_3$, are separated, and the hydroxide is precipitated by crystallization at low temperatures in stainless steel vessels. The crystals are removed from the mother lye by centrifugation.

Another industrial method is based on the oxidation of a barium sulfide solution [96 – 98]. Air is passed into the stirred solution containing barium hydroxide and barium hydrosulfide, the hydrolysis products of barium sulfide, until the hydrosulfide is oxidized to form polysulfide. Then the barium hydroxide octahydrate is crystallized at low temperatures and separated with a centrifuge. The polysulfidic mother liquor is partly recycled; the rest is usually processed into other barium compounds. The advantage of this procedure over the direct reaction of BaS solu-

tions with NaOH is the lower strontium content of the barium hydroxide product.

The monohydrate is generally produced on a commercial scale by dehydration of the octahydrate in heated vacuum driers. A monohydrate of especially high reactivity is obtained with drum driers [99]. This highly reactive monohydrate is particularly suitable for the production of oil additives, PVC stabilizers, and catalysts.

Storage, Packing, Shipping. Both the monohydrate and the octahydrate are packed and stored in 25 or 50 kg polyethylene-lined multilayer paper bags or in big bags. Shipping is governed by IMDG Class 6.1, UN 1564, or RID/ADR Class 6.1, 60c.

Uses. Barium hydroxide, especially the monohydrate, is used to produce organic barium compounds such as additives for oil and stabilizers for plastics. In addition, barium hydroxide is used for dehydration and deacidification, especially for removing sulfuric acid from fats, oils, waxes, and glycerol. In some applications, e.g., removal of sulfate from water and as starting material for other barium compounds, barium hydroxide to some extent replaces barium carbonate. The earlier use of the hydroxide in some countries for extracting the residual sucrose from molasses is no longer of much significance. The patent literature describes a procedure in which barium hydroxide is reacted with hydrogen peroxide to produce barium peroxide monohydrate [100].

2.10. Barium Nitrate

Barium nitrate [*10022-31-8*], $Ba(NO_3)_2$, M_r 261.34, *mp* 593 °C, colorless cubic crystals, often octahedra, ϱ_{20} 3.24 g/cm^3. The solubility of barium nitrate in water increases with temperature:

°C	0	10	20	50	100
wt % $Ba(NO_3)_2$	4.8	6.5	8.4	14.6	25.4

On heating, barium nitrate decomposes into barium oxide, barium peroxide, nitric oxide, nitrogen, and oxygen. The gaseous products formed and their proportions depend largely on the temperature and rate of heating [101]. The presence of sulfur or organic substances may cause an explosion.

For the *production* of barium nitrate, various procedures are possible, starting from $BaCO_3$, $Ba(OH)_2 \cdot 8\,H_2O$, BaS, or $BaCl_2$. However, for industrial production there are two main procedures. In the first, barium carbonate is suspended in recycled mother lye and reacted with nitric acid. If necessary, heavy metals are precipitated, and the solution is filtered hot. The nitrate is then crystallized, if necessary with vacuum evaporation. The second procedure consists of reacting a barium sulfide solution, directly or after the removal of barium hydroxide, with nitric acid. After carefully removing any sulfur formed and the heavy metals, the barium nitrate is crystallized at low temperatures.

The preparation of $Ba(NO_3)_2$ by double conversion of barium chloride and sodium nitrate or calcium nitrate is described in the Eastern European patent literature.

Barium nitrate is packed and stored in 25 kg polyethylene-lined multilayer paper bags. Shipping is governed by IMDG Class 5.1, UN 1446, or RID/ADR Class 5.1, 29b.

One of the main uses, as a component in pyrotechnics to produce a green color, requires very pure barium nitrate, 99.5–99.8 %. The content of other flame colorants — sodium, strontium, calcium — must be extremely low. Barium nitrate is used as a plaining agent in the manufacture of special glasses and optical glasses in place of the combination alkali-metal nitrate – arsenic. In addition it is used to incorporate barium oxide into catalysts, in luminescent cathode-ray screens, and as a component of metallurgical hardening agents.

2.11. Barium Titanate

Barium titanate [*12047-27-7*], $BaTiO_3$, M_r 233.24, *mp* 1625 °C, ϱ_{20} 6.02 g/cm^3, has phase transitions and both ferroelectric and piezoelectric properties (→ Ferroelectrics; → Insulation, Electric).

2.12. Barium Salts of Organic Acids

Barium acetate is used as a mordant in the printing industry and as a catalyst in organic chemistry.

Barium stearate is used as a slip agent in plastics and metal working, as a stabilizer against heat and light in PVC, and also in the production of grease.

The compound known as barium octoate is normally the barium salt of 2-ethylhexanoic acid. It is used as a siccative (drying agent) for the curing of alkyd paints. Siccatives catalyze the reaction between double bonds of the resin and atmospheric oxygen.

Certain dyes and pigments, also known as lakes, contain barium either as the salt of a carboxylic acid group or of a sulfonic acid group within the molecule. Well-known examples are the β-naphthol azo pigments [102].

3. Barium in the Environment

The terrestrial abundance of barium is approximately 250 g/t [10]. The estimated average barium concentration in the soil is 500 g/t [103]. Measured concentrations range between 100 and 3000 g/t [104].

Barium occurs in seawater in a concentration of 6 µg/L [105]. This level is due to reaction between barium and sulfate ions also present in the oceans. The concentration of barium is higher in deep ocean waters than in surface ocean waters [11]. The precipitated barium sulfate forms a permanent part of the sediment on the ocean floor [106]. In fresh water the barium content depends upon the occurrence of barium and the concentration of anions which form barium salts of low solubility such as sulfate and carbonate ions. Values between 7 and 15 000 µg/L (average: 50 µg/L) have been reported [107].

Studies of drinking water gave a wide range of values between only traces and 10 000 µg/L in the USA [119], 5–600 µg/L in Canada [120], and 1–20 µg/L in municipal drinking waters in Sweden [107].

Barium levels in the air are not well documented. An estimate of a mean value for the USA is 0.05 µg/L [121]. There is no correlation between the degree of industrialization and the barium concentration in the air. Higher levels are found in areas with high natural dust levels. Anthropogenic emissions are primarily industrial. Reports about the release of barium by way of exhaust gases, mainly from diesel engines [122, 123], are no longer valid since in the last few years the primary cause, namely, the sulfur content of diesel fuels, has been reduced due to legislation. Therefore, there is no longer a need to use barium compounds as sulfur-scavenging fuel additives. Other atmospheric emissions result from the handling of barium compounds or materials containing barium compounds, such welding wires [124].

4. Dietary Intake of Barium

Figures for the mean dietary intake of barium in the USA ranged from 300 to 1700 µg/d [125] and 650 to 1770 µg/d in two other studies [126]. These results match well with barium intakes in other parts of the world [127] with reported levels between 80 and 1330 µg/d. Apart from drinking water, milk, potatoes, and flour have been suggested to be the main sources for barium in the diet [128], even though absolute barium concentrations are higher in, for example, eggs and certain types of cheese. The normal dietary intake of barium within these limits is apparently harmless to humans. Acute symptoms will, however occur in case of an overdose of bioavailable barium (see Chap. 5). There is no evidence that barium is carcinogenic [121].

Typical levels of barium in human tissues and blood [11]: 3–70 ppm in the bone; 0.04–1.2 ppm in the liver; 0.09 ppm in the muscle, and 0.06 mg/dm^3 in the blood. The total mass average for a 70-kg human is 22 mg.

5. Toxicology

Water-soluble barium compounds are toxic, as is shown in Table 4. Most barium poisonings are caused by mistaking soluble barium compounds, such as barium carbonate, for the insoluble — and therefore nontoxic — barium sulfate, which is used as a contrast agent in X-ray diagnosis.

The symptoms of poisoning are convulsions of both striated and smooth muscles, including the heart, followed by paralysis of the peripheral nerve system. These effects on the nerve system are accompanied by severe inflammation of the gastrointestinal tract.

Table 4. Acute lethal doses of soluble barium compounds

Compound	Toxicity	Ref.
Barium carbonate [*513-77-9*]	TDLo 29 mg/kg (human, oral)	[108]
Barium nitrate [*10022-31-8*]	LD_{50} 8.5 mg/kg (mouse, i.v.)	[109]
	LD_{50} 355 mg/kg (rat, oral)	[110]
Barium chloride [*10361-37-2*]	LDLo 11.4 mg/kg (human, oral)	[111]
Barium oxide [*1304-28-5*]	LD_{50} 50 mg/kg (mouse, subcutaneous)	[112]
Barium fluoride [*7787-32-8*]	LD_{50} 250 mg/kg (rat, oral)	[113]

Barium carbonate is often used in the ceramics industry. Detailed examination of workers exposed to $BaCO_3$ dust for 7–27 years did not reveal any specific chronic poisoning [114]. Damage to the lungs has been reported to have been caused by contaminants in the barium compounds, such as quartz [115] or zinc sulfide [116]. However, $BaSO_4$ may cause a benign pneumoconiosis (barytosis) because, unlike $BaCO_3$, $BaSO_4$ is not absorbed by the organism [117, 118]. The legally binding "Permissible Exposure Limit" (PEL) for $BaSO_4$ dust in the USA is 15 mg/m^3, whereas the voluntary "Threshold Limit Value" (TLV) was set to 10 mg/m^3. The German MAK value for $BaSO_4$ dust is 3 mg/m^3.

For soluble barium compounds, an exposure limit of 0.5 mg/m^3 (as Ba) has been established by both TLV (1989) and MAK (1996) commissions. According to the MAK, short-term exposure limits may be as high as 1 mg/m^3 (average over 30 min, four times within 8 h).

1. Introduction

Batteries and fuel cells are electrochemical energy converters that directly convert chemical into electrical energy. In batteries the energy is generally stored within the electrodes. But there are exceptions, e.g., the air – zinc system, where one of the reacting substances is continuously supplied from outside, or the zinc – bromine system, where the active material is stored in separate tanks. *Fuel cells* receive their chemical energy from outside sources (→ Fuel Cells).

Batteries can be recharged, if they represent reversible systems. This, however, often is restricted, since not only the system's electrochemical reactions must be reversible, but also the structure of its electrodes. As a consequence, two basically different battery systems exist, i.e., primary and secondary batteries:

1) *Primary batteries* are designed to convert their chemical energy into electrical energy only once.
2) *Secondary batteries* are reversible energy converters and designed for many cycles, i.e., repeated discharges and charges.

The border between both types is blurred, since some primary battery systems permit charging under certain, but usually limited conditions. In general, the efficiency of their recharging process is poor and often results in early failure. The IEC therefore does not recommend the charging of any primary system [1], [2].

Batteries are of increasing importance in all areas of our daily life. They are fabricated in very large ranges of system, volume, weight, and construction. Batteries may be purchased as small button cells, that may have volumes of well below 1 cm^3 to operate a wrist watch, a pocket calculator, a hearing aid, or another small electronic device. Other types of batteries power large electric vehicles including trains and ships, and may have a volume of the order of cubic meters and a weight of several tons. In between a huge variety of batteries exists, designed for all kinds of applications. To meet all needs of the market, batteries offer a large range of optimized properties regarding electric energy, voltage, power output, self-discharge, environmental compatibility, and price.

The term "direct energy conversion" indicates that also nondirect energy conversion systems exist. A famous example is the combustion engine, which converts chemical into mechanical energy via a thermal process (Carnot process) and which may serve for a simplified comparison. Both systems are characterized by a reducing agent and an oxidizing agent. In the case of the combustion engine the reducing agent is the fuel and the oxidizing agent usually atmospheric oxygen. A battery is also characterized by a reducing agent ("fuel") and an oxidizing agent, that serve as energy storage. A well known fuel of this kind is metallic zinc (representing the negative electrode of, e.g., a flashlight battery), and the corresponding oxidant is manganese dioxide, constituting the positive electrode of that battery.

Figure 1. Electrochemical cell and the split-up of the cell reaction
$S(N)_{red}$ and $S(P)_{ox}$ are the reacting components of the negative and the positive electrode, respectively. The shown reactions apply when the battery is discharged.

In principle, direct and nondirect chemical energy conversion are comparable: In both cases the reductant is oxidized under consumption of the oxidant, the latter being stored inside or outside the system (e.g., air). However, the direct energy conversion is not restricted by the limited efficiency of the Carnot process of the combustion engine. In the battery the reaction is split up into one that releases electrons (which means oxidation), and another one that absorbs electrons (which means reduction) (see Fig. 1). The electron exchange that is connected with these reactions, can so be transformed directly into a

current that flows through the electrical appliance (or the charging device).

In principle, a large range of "fuels" and "oxidants" exists for electrochemical energy storage and conversion, each combination representing a new battery system. However, not all combinations are meaningful. A careful selection has to be made, also with respect to the type of electrolyte being employed.

2. History

The history of batteries is usually traced back to Luigi Galvani (1737 – 1798), who detected electrical phenomena between different metals in his famous experiments with frog legs. Allessandro Volta (1745 – 1827) built the first primary battery, the so-called Volta pile. The scientific foundation of electrochemical energy storage was derived by Michael Faraday (1791 – 1867).

The early development of *secondary batteries* is connected to names like Gaston Planté (1834 – 1899), Camille Alfons Faure (1840 – 1898), and Henry Owen Tudor (1859 – 1928) in the field of the lead – acid battery, while Thomas Alva Edison (1847 – 1931) and Valdemar Jungner (1869 – 1924) are the two important names in connection with nickel – iron and nickel – cadmium batteries.

In the decades following these discoveries the lead – acid and the nickel – cadmium system were constantly improved. Today's motor cars would be unthinkable without their reliable batteries. Sealed nickel – cadmium batteries supply the energy for many of our portable electronic devices, and valve-regulated lead – acid batteries have gained a large share of the market for standby batteries.

In the 1990s new rechargeable systems appeared on the market. Of special importance are the nickel – metal hydride and the lithium-ion system.

Primary batteries for practical use emerged in the middle of the 19th century. Special reference is made to George Leclanché, who pioneered the 1.5 V manganese dioxide – zinc system with aqueous ammonium chloride as electrolyte. This system was described first by him in 1866 [3]. It is still produced, technically much more advanced by now, of course, but still known as Leclanché or zinc-carbon battery.

Over the years another 1.5 V system became most successful. It is the alkaline version of the manganese dioxide – zinc system, first proposed in 1882. Its development was taken up again by W. S. Herbert [4], [5] about 70 years later. It took, however, another 20 years before the system became commercially available.

Further to be mentioned is the alkaline silver oxide – zinc system. First patents date back to 1883 – 1910 [6]. This 1.5 V battery is an expensive system, which, however, exhibits very favorable electrochemical properties. To become successful it needed a market for small batteries which opened up in 1975 with the introduction of microelectronics (e.g., wrist watches).

Another primary system that deserves mentioning is the air – zinc system. H. Cohen [7] was the first to develop a practical carbon – zinc element with aqueous ammonium chloride as electrolyte and air as oxidant in 1891. The system is still in use. Its main application is in the area of low power output over a long period of time (e.g., electric fence controllers).

Special future promise has the alkaline air – zinc version. C. Féry was obviously the first [8] to realize this system in 1925. Owing to further development the alkaline zinc – air element offers the highest energy density of all currently available battery systems. Since the alkaline air – zinc battery is also an environmentally benign system, it has replaced the mercuric oxide – zinc system in important application areas, e.g., hearing aids. After activation, however, its storage behavior is limited, depending on construction (e.g., air access) and environment (e.g., humidity).

Finally there are primary battery systems using nonaqueous electrolytes, i.e., lithium batteries. Research activities to develop high energy lithium systems started in about 1960, especially in the USA and soon spread worldwide. Of the many lithium systems developed since the 1960s, about ten systems have attained market relevance (see Section 6.2).

For a more detailed description of the history of batteries, see, e.g., [9–11].

3. Fundamental Laws

Direct conversion of chemical into electrical energy requires the split-up of the electrochemical reactions into reactions of reductants that deliver electrons and reactions of oxidants that accept electrons. Such a split-up is achieved in the electrochemical cell, shown in Figure 1. A positive and a negative electrode are immersed in the electrolyte and the reacting substances (the active materials) are usually stored in the electrodes and the electrolyte, if it participates in the overall reaction.

During discharge, oxidation of $S(N)_{red}$ occurs at the negative electrode according to

$$S(N)_{red} \longrightarrow S(N)_{ox} + n \cdot e^-$$

while $S(P)_{ox}$ is reduced at the positive electrode:

$$S(P)_{ox} + n \cdot e^- \longrightarrow S(P)_{red}$$

Both together form the cell reaction

$$S(N)_{red} + S(P)_{ox} \longrightarrow S(N)_{ox} + S(P)_{red} + \text{energy}$$

When the battery is charged, this reaction is reversed and energy has to be supplied to the cell.

The arrangement shown in Figure 1 resembles an electrolytic capacitor where also two electrodes are separated by the electrolyte. However, charging and discharging of such a capacitor involves only charge shifting within the double layer at the electrode – electrolyte interface. Chemical reactions do not occur and the physical structure of the electrodes is not affected. For this reason, a nearly unlimited number of charge – discharge cycles are possible. Since mass transport does not occur, charge and discharge of a capacitor occur extremely fast, but the amount of stored energy per weight or volume is comparatively small.

In batteries, such a double layer also exists, and the large surface area of the active material gives rise to a high double-layer capacitance that is observed when impedance measurements are made. The double-layer capacitance is caused by charge shifting and is given in the unit Farad, i.e., As/V. The real battery capacity, however, is based on chemical reactions and measured as As or Ah. (Actually, the double-layer capacity is always involved when a battery is charged or discharged). Each charge – discharge cycle changes the physical structure of the electrodes, and these changes inevitably cause an aging processes. Thus, with a battery the number of possible charge – discharge cycles is inevitably limited, and performance changes during service live are unavoidable.

The *cell reaction* characterizes each battery system and its components that represent the charged and discharged states determine the amount of energy that can be stored. As a consequence, the parameters of its cell reaction are of paramount importance for the battery system. While for primary batteries only reactions are relevant that describe the open circuit voltage and the discharge behavior, for rechargeable batteries these reactions must be reversible.

In the following, a brief survey is given of the most important rules. For details and derivations, see textbooks of electrochemistry or fundamental books on batteries, e.g., [12–17].

3.1. Equilibrium or Thermodynamic Parameters

The laws of thermodynamics generally apply to the state of equilibrium, which means that all reactions are balanced. In the electrochemical cell, equilibrium data can only be measured when no current flows through the cell or its electrodes. On account of this balance, the thermodynamic parameters do not depend on the reaction path but only on the difference in energy levels between the final and initial components of the system (the products and the reactants of the electrochemical reaction). The thermodynamic parameters describe the maximally achievable performance data. As soon as current flows through the cell, these values are lowered, owing to kinetic parameters.

The main thermodynamic parameters of an electrochemical reaction are:

1) The *enthalpy of reaction* ΔH which represents the amount of energy released or absorbed. ΔH describes the heat that is generated, provided that 100 % of the chemical energy is converted into heat.
2) The *free enthalpy of reaction* ΔG, also called *change of Gibbs free energy* ΔG, which describes the (maximum) amount of chemical energy that, under equilibrium conditions,

can be converted into electrical or mechanical energy and vice versa.

3) *The entropy of reaction* ΔS which characterizes the reversible heat effect $T \cdot \Delta S$ (where T = temperature in kelvins) which describes the energy loss or gain connected with any chemical or electrochemical process under equilibrium conditions.

Important relations between the three parameters are:

$$\Delta G = \Delta \mathrm{H} - T \cdot \Delta S \text{ or } \Delta H - \Delta \mathrm{G} = T \cdot \Delta S \quad (3.1)$$

The difference between ΔH and ΔG, the product $T \cdot \Delta S$, is the aforementioned reversible heat effect. $T \cdot \Delta S$ can be positive or negative. In the first case, additional energy is generated by cooling of the environment (Peltier or heat pump effect). Otherwise, $T \cdot \Delta S$ constitutes an additional heat increment.

The equilibrium voltage U^{o} is given by

$$U^{\mathrm{o}} = -\frac{\Delta G}{n \cdot F} \quad (3.2)$$

where n is the number of exchanged electronic charges; F the Faraday constant (96 485 As/equivalent; i.e., 26.802 Ah/equivalent); $n \cdot F$ denotes the amount of electrical charge connected with the reaction; and $n \cdot F \cdot U^{\mathrm{o}}$ describes the generated electrical energy (kJ). Thermodynamic quantities like ΔH and ΔG depend on the concentrations (or, more accurately, activities) of the reacting components, as far as these components are in solution. The corresponding relation is:

$$\Delta G = \Delta G^{\mathrm{o,s}} + R \cdot T \cdot \left(\sum \ln \left[(a_i)^{j_i} \right]_{\mathrm{prod}} - \sum \ln \left[(a_i)^{j_i} \right]_{\mathrm{react}} \right) \quad (3.3)$$

where a_i is the activity of the reacting component i (approximately its concentration) in mol/cm^3); j_i is the number of equivalents of this component that take part in the reaction; R is the molar gas constant for an ideal gas (R = 8.3145 JK^{-1} mol^{-1}); $\Delta G^{\mathrm{o,s}}$ is the standard free enthalpy value when all activities are unity. The terms "reac" and "prod" designate in the formula reactants and products for the forward (spontaneous) reaction. Combination of Equation (3.2) and Equation (3.3) results in the Nernst Equation:

$$U^{\mathrm{o}} = U^{\mathrm{o,s}} - \frac{R \cdot T}{n \cdot F} \cdot \ln \frac{\Pi \, (a_i)^j_{\mathrm{react}}}{\Pi \, (a_i)^j_{\mathrm{prod}}} \quad (3.4)$$

which is simplified for 25 °C (298.2 K) to

$$U^{\mathrm{o}} = U^{\mathrm{o,s}} - \frac{0.0592}{n} \cdot \log \frac{\Pi \, (a_i)^j_{\mathrm{react}}}{\Pi \, (a_i)^j_{\mathrm{prod}}} \quad (3.5)$$

under consideration that

$$\ln(..) = 2.303 \log(..),$$

$$R = 8.3145 JK^{-1} mol^{-1} = 8.3145 WsK^{-1} mol^{-1},$$

and

$$F = 96485 As/equiv.$$

thus

$R \cdot T/F$ = 0.02569 V · equiv. · mol^{-1} (T = 298.16 K)

or

2.303 · $R \cdot T/F$ = 0.0592 V · equiv. · mol^{-1}.

The thermodynamic data also determine the temperature coefficient of the equilibrium cell voltage according to:

$$\frac{\mathrm{d}U^{\mathrm{o}}}{\mathrm{d}T} = -\frac{\Delta S}{n \cdot F} \quad (3.6)$$

Single Electrode Potentials. Thermodynamic calculations are always based on an electrochemical cell reaction and the derived voltage and its temperature coefficient in fact concern the voltage difference between two electrodes. The voltage difference between the electrode and the electrolyte, the *absolute potential*, cannot be determined exactly, since potential differences can only be measured between two electronic conductors [18]. Thus, single electrode potential always means the cell voltage between the electrode in question and a reference electrode. To provide a basis for the electrode-potential scale, the zero point was arbitrarily equated with the potential of the *standard hydrogen electrode* (SHE), a hydrogen electrode under specified conditions at 25 °C [19].

Hydrogen reference electrodes are not used in battery practice. They are not only impracticable to handle but also involve some risk

of contamination of the battery's electrodes by the noble metals like platinum or palladium used as electrode materials in the hydrogen electrode [20]. Therefore, a number of reference electrodes are used instead, e.g., the *mercury/mercury(I) sulfate reference electrode* (Hg/Hg_2SO_4) in lead – acid batteries, and the *mercury/mercury(II) oxide reference electrode* (Hg/HgO) in alkaline solutions (cf., e.g. [21]). In lithium-ion batteries with organic electrolytes, the electrode potential is mostly referred to that of the lithium electrode.

3.2. Current Flow, Kinetic Parameters

When current flows, the cell reaction must occur at a corresponding rate. This means that electron transfer has to be forced into the desired direction, and mass transport is required to bring the reacting ions to the electrode surface or carry them away. To achieve this current flow, additional energy is required. This energy finds its expression in *overvoltages*, i.e., deviations from the equilibrium voltage (sometimes denoted as "irreversible entropy loss" $T \cdot \Delta S_{\mathrm{irr}}$). Furthermore, current flow through conducting elements causes *ohmic voltage drops*. Both mean irreversible energy loss and a corresponding heat generation, caused by current flow.

As a result, the voltage U under current flow i is reduced (on discharge) or increased (secondary cellon charge) compared to the equilibrium value U°. The difference $U - U^{\circ}$, when measured as deviation from the cell voltage comprises:

1) The overvoltage, caused by electrochemical reactions and concentration deviations on account of transport phenomena.
2) The ohmic voltage drops, caused by the electronic as well as the ionic currents in the conducting parts including the electrolyte.

The sum of all the voltage drops caused by the current flow is called *polarization*, i.e.,

$$\text{polarization} = \text{overvoltage} + \text{ohmic voltage drops} \tag{3.7}$$

The quantity determined in practice is always polarization. Overvoltage can be determined separately only by special electrochemical methods.

Usually, the reaction path consists of a number of reaction steps that precede or follow the actual charge transfer step as indicated in Figure 2.

Figure 2. Course of an electrochemical reaction. Charge transfer often can only occur with adsorbed species, then adsorption/desorption steps are included. Furthermore, chemical reactions may precede or follow the electron transfer step.

The rate of each of these reaction steps is determined by kinetic parameters, such as exchange current density, diffusion coefficients, or transport numbers. The slowest partial step of this chain is decisive for the rate of the overall reaction. As a consequence, overvoltages, or even limitations of the reaction rate, often are not caused by the electron-transfer step itself, but by preceding or following steps.

Transport of the reacting species is achieved by two mechanisms, diffusion and migration, and, when only one-dimensional transport is assumed, is given by:

$$N_j = \frac{i_j}{n \cdot F} = -D_j \frac{\partial c_j}{\partial \zeta} + \frac{i \cdot t_j}{z_j \cdot F} \tag{3.8}$$

where N_j is the flux of species j in mol/cm^2; i_j/nF the current equivalent; c_j the concentration of species j in mol/cm^3; $\delta c_j/\delta\zeta$ the concentration gradient in mol/cm^4; D the diffusion coefficient in cm^2/s; t the transference number; z_j the valence number (charges per ion i); and ζ the diffusion direction (cm). Addend 1 describes mass transport by diffusion, which is proportional to the (negative) gradient of the concentration $\mathrm{d}c_j/\mathrm{d}\zeta$ that often can be approximated as a linear slope $\Delta c = c_j - c_{\mathrm{j,o}}$ where c_j is the concentration of the concerned species at the electrode surface, while $c_{j,\mathrm{o}}$ denotes the corresponding concentration in the bulk of the electrolyte.

Diffusion can limit the reaction rate when the mass transport by diffusion precedes the electron transfer step. If the concentration c_j attains the value zero at the electrode surface, all the arriving ions or molecules are charged or discharged immediately, and further increase of the current by increased overvoltage is not possible. Thus the current cannot exceed a certain value, the *limiting current* (i_{lim}) that can be derived from the first term in Equation (3.8) with $c_j = 0$.

Addend 2 in Equation (3.8) describes ion transport by migration by the ionic current. The transference number t denotes the share of the total current that is carried by the corresponding ionic species. In a binary electrolyte, dissociated into A^+ and B^-, the transference numbers are related by

$$t_+ + t_- = 1 \tag{3.9}$$

Transference numbers depend on the concentration of the ions and on temperature. In binary-salt solutions they are fairly close to 0.5, which means that both ion species more or less equally share in ion conductivity. Larger deviations are observed in acids and bases on account of the much higher ion mobility of H^+ and OH^- ions. The values for the battery electrolytes sulfuric acid (dissociated into H^+ and HSO_4^-) and potassium hydroxide are:

Sulfuric acid	$t_+ = t_{\mathrm{H}^+} = 0.9$	$t_- = t_{\mathrm{HSO}_4^-} = 0.1$
Potassium hydroxide	$t_+ = t_{\mathrm{K}^+} = 0.22$	$t_- = t_{\mathrm{OH}^-} = 0.78$

These transference numbers for sulfuric acid, given in [19, p. 255] for diluted solutions, are also true for concentrations used in batteries. The numbers for potassium hydroxide are valid for a wide concentration range [22].

The transference number indicates how much the concentration of the concerned ion is changed by migration due to the current flow. The small value for the HSO_4^- ion means that its concentration is only slightly influenced by migration. In lithium ion batteries, where lithium ions swing between the negative and the positive electrode, a transference number $t_{\mathrm{Li}} = 1$ would be desirable, since then a constant concentration profile would be maintained during discharging and charging. This is one reason to aim at utilization of conducting salts with large anions in such systems as mentioned in Section 7.2.1.4.4.

3.2.1. Electron Transfer

The electron transfer reaction denotes the central reaction step where electric charge is exchanged (cf. Fig. 2). Current flow affords additional forces because of an energy barrier that has to be surmounted by electrons. The required additional energy is the activation energy and the dependence of reaction rates on the activation energy is expressed by the Arrhenius equation

$$k = k_{\mathrm{o}} \cdot \exp\left(-\frac{E_{\mathrm{A}}}{R \cdot T}\right) \tag{3.10}$$

where k is the reaction constant and E_{A} the activation energy (J/mol). In electrode reactions, $n \cdot U \cdot F$ is the driving force, and the corresponding relation is:

$$i = k\prime \cdot c_j \cdot \exp\left(\frac{n \cdot F}{R \cdot T} U\right) \tag{3.11}$$

k' includes the "equivalence factor" $n \cdot F$ between mass transport and current i, U is the electrode potential, and c_j the concentration of the reacting substance that releases or absorbs electrons. Electron transfer, however, does not occur only in one direction: the reverse reaction is possible as well, and the balance between both depends on the electrode potential. Thus, Equation (3.11) has to be completed.

$$i = k_+ \cdot c_{\mathrm{red}} \cdot \exp\left(\frac{\alpha \cdot n \cdot f}{R \cdot T} U\right) - k_- \cdot c_{\mathrm{ox}} \cdot \exp\left(-\frac{(1-\alpha) \cdot n \cdot F}{R \cdot T} U\right) \tag{3.12}$$

where addend 1 describes the anodic reaction (e.g., $Pb \rightarrow Pb^{2+}$), addend 2 its reversal; a denotes the transference factor (usually ≈ 0.5) that indicates how symmetrically the reaction and its reversal depend on electrode potential (difference in activation energies); n is the number of charges, and c_{red}, c_{ox} are the concentrations of the reduced and oxidized states of the reactants. Such an electron transfer occurs also during equilibrium at equal rates in both directions as a dynamic equilibrium, although no current flow is observed through the electrodes. The equilibrium voltage (U^{o}) is determined by the point at which the forward and reverse reaction rates equal each other.

At the equilibrium potential $U = U^{o}$, the current flow in both directions is balanced, which means

$$i_{+}(0) = -i_{-}(0) = i_{o}$$

This balancing current is called *exchange-current density* (it is necessarily related to the surface area, therefore it is a current density given, e.g., in mA/cm^2. In battery practice, such current densities often are referred to the nominal capacity (Ah or 100 Ah, because the true surface area of the porous material is not known, but there is a certain relation between surface area and nominal capacity). Often the current-voltage curves are related to the deviation from the equilibrium potential, the overvoltage $\eta = U - U^{o}$. This leads to the usual form of Equation (3.12):

$$i = i_{o} \left[\exp\left(\frac{\alpha \cdot n \cdot F}{R \cdot T}\eta\right) - \exp\left(-\frac{(1-\alpha)\cdot n \cdot F}{R \cdot T}\eta\right)\right] \quad (3.13)$$

where i_{o} is the exchange current density that characterizes the dynamic equilibrium as shown in Figure 3. The resulting current is represented in Figure 3 by the solid curve as the combination of anodic and cathodic current-voltage curves.

Figure 3. The current voltage curve. The horizontal axis (abscissa) represents the overvoltage $\eta = U - U^{o}$; The vertical axis (ordinate) the current density i, which is synonymous to the reaction rate; i_0 is the exchange current density that characterizes the dynamic equilibrium. The reaction of the lead electrode is inserted as an example.

Polarization. Polarization is an important parameter given by the relations

$$\eta_{+} = U_{+} - U_{+}^{o} \text{ or } \eta_{-} = U_{-} - U_{-}^{o} \quad (3.14)$$

where η_{+} and η_{-} are the polarization of the positive and negative electrodes, respectively; U_{+} and U_{-} are the actual potentials; and U_{+}^{o} and U_{-}^{o} the equilibrium potentials of the positive and negative electrodes. The cell voltage $U_{+} - U_{-}$ results in

$$U = U^{o} + \eta_{+} - \eta_{-} \quad (3.15)$$

According to the definition in Equation (3.14), the polarization of the negative electrode has a negative sign when the electrode potential is below its equilibrium value. If the cell voltage is considered, η_{+} and η_{-} are summed up to η.

Polarization is a very important parameter. The negative electrode is only kept fully charged when its polarization is negative or zero ($\eta_{-} \leq 0$) while for a charged positive electrode a positive polarization is required ($\eta_{+} \geq 0$).

3.2.2. Tafel Lines

If the potential is shifted far enough from the equilibrium value, the reverse reaction can be neglected in Equation (3.13). Then the resulting current – voltage curve in Figure 3 becomes a simple exponential function

$$i = i_{o} \cdot \exp\left[\frac{\alpha \cdot n \cdot F}{R \cdot T} \cdot \eta\right] \quad (3.16)$$

This equation can be rearranged into

$$\eta = \frac{R \cdot T}{\alpha \cdot n \cdot F} \cdot \ln(|i|) - \frac{R \cdot T}{\alpha \cdot n \cdot F} \cdot \ln(|i_{o}|) \quad (3.17)$$

that can be written in a form known as the Tafel equation (J. Tafel was the first to describe this relation in connection with hydrogen-overvoltage measurements on noble metals [23])

$$\eta = a + b \cdot \log(|i|) \quad (3.18)$$

The curves represented by Equation (3.18) are linearized when plotted semi-logarithmically and are called *Tafel lines*. The constant b represents the slope of the Tafel line and denotes the potential difference that causes a current increase of one decade. Tafel lines are important tools when reactions are considered that occur at high overvoltages, since such a linearization allows quantitative considerations (cf. Fig. 65).

3.2.3. Influence of Temperature

Temperature is an important parameter for all electrochemical reaction rates. In general, the approximation can be used that the rates of electrochemical reactions like hydrogen evolution, oxygen evolution, and corrosion are doubled per temperature increase of 10 °C. Then the corresponding Tafel lines are shifted upwards in parallel.

3.3. Heat Effects

Like chemical reactions electrochemical reactions are always connected with heat effects, determined by the reversible heat effect, mentioned in Equation (3.1). When current flows through the cell, additional heat is generated by overvoltages due to kinetic parameters and by ohmic resistances in the electrodes. The sum of both is the polarization that causes the Joule effect (Section 3.3.2).

3.3.1. Reversible Heat Effect

The reversible heat effect

$$Q_{\mathrm{rev}} = T \cdot \Delta S \tag{3.19}$$

represents an unavoidable heat absorption or heat emission that is connected with electrochemical reactions. It is related to the thermodynamic (equilibrium) parameters of the concerned reaction, and is strictly connected with the amount of material (in electrochemical equivalents) that reacts. Thus, the reversible heat effect does not depend on discharge or recharge rates. When the cell reaction is reversed, the reversible heat effect is reversed too, i.e., it acquires the opposite sign. Thus, energy loss in one direction means energy gain when the reaction is reversed. The reversible heat effect per unit time can be related to current flow, because each multiple of the cell reaction requires the current amount $n \cdot F$:

$$\frac{\mathrm{d}Q_{\mathrm{rev}}}{\mathrm{d}t} = \frac{Q_{\mathrm{rev}}}{n \cdot F} \cdot i \tag{3.20}$$

Q_{rev}/nF has the unit volts. So it is equivalent to a voltage, although it is not a voltage that can be measured, but for caloric evaluations it is convenient to combine U^{o} with Q_{rev}/nF. The difference

$$U_{\mathrm{cal}} = U^{\mathrm{o}} - \frac{Q_{\mathrm{rev}}}{n \cdot F} \tag{3.21}$$

is called calorific voltage (or *thermoneutral* potential E_{tp} [24]). U_{cal} is a hypothetical voltage that includes the reversible heat effect, and is used instead of the equilibrium voltage for caloric calculations. The combination with Equations (3.1) and (3.2) shows that U_{cal} also can be written as

$$U_{\mathrm{cal}} = -\frac{\Delta H}{n \cdot F}$$

3.3.2. Current Related Heat Effects (Joule Effect)

Current flow through any conducting object generates heat proportional to the voltage drop caused by the current itself according to

$$\mathrm{d}Q_{\mathrm{Joule}}/\mathrm{d}t = \Delta U \cdot i \tag{3.22}$$

This heat is called the Joule effect; it always means loss of energy.

Strictly speaking, the negative absolute value should be used in Equation (3.22) for consistency with the arithmetical sign of the thermodynamic parameters (lost energy always has a negative sign).

In an electrochemical cell, the voltage drop caused by the current is represented by the difference between the cell voltage under current flow U and the open-circuit cell voltage U^{o}. Then the Joule effect reads according to Equation (3.22):

$$\mathrm{d}Q_{\mathrm{Joule}}/\mathrm{d}t = (U - U^{\mathrm{o}}) \cdot i \tag{3.23}$$

or its integrated form for a period t (in hours)

$$Q_{\mathrm{Joule}} = \int_0^t \{(U - U^{\mathrm{o}}) \cdot i\} \, \mathrm{d}t \tag{3.24}$$

Strictly speaking Equation (3.23) describes a composite parameter of

1) The "genuine" Joule effect $dQ/dt = i^2 \cdot R$, which describes the heat generation by current flow (i) through the ohmic resistance (R) of the conducting elements and the electrolyte, and

2) The irreversible heat effect $T \cdot \Delta S_{irr}$, which causes voltage drops between the electrode surface and the electrolyte on account of reaction hindrance (overvoltage according to Eq. 3.7). This additional heat is caused by an additional entropy of reaction (ΔS_{irr}) which cannot be recouped when the reaction is reversed.

For heat effects this is not relevant, since heat generation is proportional to polarization.

$U - U^{\mathrm{o}}$ does not remain constant during charging or discharging, because it is related to the internal resistance, that usually increases with proceeding discharge, because of the lower conductivity of the discharged products. In lead – acid batteries the conductivity of the electrolyte also decreases with discharge, and acid dilution also influences U^{o}. In quite a number of battery systems the U^{o}-value is also influenced by the state of charge. An example is the manganese dioxide – zinc system [25].

3.3.3. Heat Generation in Total

Summation of the Joule effect and the reversible heat effect gives the total heat generated in the cell or the battery, i.e.,

$$Q_{\mathrm{total}} = Q_{\mathrm{Joule}} + Q_{\mathrm{rev}} \tag{3.26}$$

as energy, e.g., Wh, or as energy per time unit, i.e., power, e.g., W,

$$\frac{\mathrm{d}Q_{\mathrm{total}}}{\mathrm{d}t} = \frac{\mathrm{d}Q_{\mathrm{Joule}}}{\mathrm{d}t} + \frac{\mathrm{d}Q_{\mathrm{rev}}}{\mathrm{d}t} \tag{3.27}$$

Depending on the sign of $\mathrm{d}Q_{\mathrm{rev}}/\mathrm{d}t$, the total energy generation may be larger or smaller than the Joule effect.

According to Equation (3.23), $\mathrm{d}Q_{\mathrm{Joule}}/\mathrm{d}t$ can be substituted by $(U - U^{\mathrm{o}}) \cdot i$, which gives:

$$\frac{\mathrm{d}Q_{\mathrm{total}}}{\mathrm{d}t} = (U - U^{\mathrm{o}}) \cdot i + \frac{\mathrm{d}Q_{\mathrm{rev}}}{\mathrm{d}t} \tag{3.28}$$

Substitution of $\mathrm{d}Q_{\mathrm{rev}}/\mathrm{d}t$ by Equation (3.20) and application of Equation (3.21) results in the simple relation that is convenient for heat calculations:

$$\frac{\mathrm{d}Q_{\mathrm{total}}}{\mathrm{d}t} = (U - U_{\mathrm{cal}}) \cdot i \tag{3.29}$$

Strictly speaking, Equation (3.29) should have a negative sign according to thermodynamic parameters, since the Joule effect is always lost energy, as mentioned in connection with Equation (3.22). To overcome this difficulty, $Q_{\mathrm{gen}} = -Q_{\mathrm{total}}$ is introduced below.

3.4. Heating of the Battery

While a battery is being charged or discharged, the heat generation caused by the flowing current raises the temperature until balance is achieved between heat generation in the cell and heat dissipation to the environment. This balance depends on both: the rate of heat generation and the possibility of heat dissipation.

Heating Effects, Heat Capacity. The change of battery temperature during discharge ($\mathrm{d}T/\mathrm{d}t$) can be estimated by heat generation values:

$$\frac{\mathrm{d}T}{\mathrm{d}t} = \frac{1}{C_{\mathrm{Batt}}} \cdot \left(\frac{\mathrm{d}Q_{\mathrm{gen}}}{\mathrm{d}t} - \frac{\mathrm{d}Q_{\mathrm{diss}}}{\mathrm{d}t} \right) \tag{3.30}$$

where $\mathrm{d}Q_{\mathrm{gen}}/\mathrm{d}t$ is the generated energy per unit time and $\mathrm{d}Q_{\mathrm{diss}}/\mathrm{d}t$ the dissipated energy per unit time; Q_{gen} corresponds to Q_{total} in Equation (3.29). C_{Batt} is the heat capacity of the battery (in kJ/K) defined by

$$\sum [m(j) \cdot C_p(j)] = C_{\mathrm{Batt}} \tag{3.31}$$

where i denotes one of the various components of the battery; $m(i)$ is the mass of component i in kg; and $C_p(i)$ is the specific heat of component i in kJ kg^{-1} K^{-1}.

4. Battery Properties and Characteristics

Figure 1 shows the basic design of a single cell. When the battery is discharged, the active material in the positive electrode is reduced

$$\mathrm{S(P)_{ox}} + n \cdot \mathrm{e}^- \longrightarrow \mathrm{S(P)_{red}}$$

Such a reducing current flow is called "cathodic".

In the negative electrode, the active material is oxidized

$$\mathrm{S(N)_{red}} \longrightarrow \mathrm{S(N)_{ox}} + n \cdot \mathrm{e}^-$$

by an "anodic" current. The terms cathodic and anodic are strictly connected to the direction of current flow. *Cathodic* means that a negative current (i.e., negatively charged ions) flows from the cathode to the anode via the electrolyte, *anodic* means a positive current (positively charged ions) flowing from the anode to the cathode via the electrolyte, i.e., in opposite direction. Thus, during charging, these currents are reversed. In accordance with these terms, in the field of *primary batteries* the positive electrode is usually called "cathode" since the positive electrode is discharged by a cathodic current, while the negative electrode is called "anode", and this is unambiguous, since only discharge occurs.

In *secondary batteries*, it depends on charge or discharge which of the two electrodes is anode or cathode. Thus, in lead – acid batteries, the negative electrode is anode during discharging ($Pb \longrightarrow Pb^{2+}$), but cathode during charging. The opposite applies to the positive electrode: $Pb^{4+} + 2 \cdot e^- \longrightarrow Pb^{2+}$ is a cathodic reaction, and the PbO_2 electrode is cathode during discharging but anode during charging. Because of this ambiguity, the terms positive electrode and negative electrode are preferred for secondary batteries.

For secondary lithium-ion batteries, however, that partially have been developed commonly with primary lithium batteries, the terms cathode and anode have become customary. Then the terms anode and cathode correspond to the discharging situation.

4.1. Cell and Battery

The basic element of each battery is the cell, corresponding to Figure 1. The term *battery* refers usually to several cells (at least two) being connected in series or in parallel. The International Electrotechnical Commission IEC, however, has meanwhile extended the term "battery" to also include single cells, if they have terminal arrangements, such that they can be placed into a battery compartment while providing adequate contact. Furthermore the single cell must carry markings as required by the IEC Standard in order to be called a battery [26], [27].

According to IEC the term *cell* still applies when referring to the component cells inside a multicell battery, like, e.g., a 9 V battery. Terms like smart batteries, battery packs, etc., are discussed in Sections 5.2.1 and 7.2.1.4.7.

4.1.1. Active Material

The term active material refers to the components of the cell reaction being used up or regenerated in consequence of a discharge or charge. The term active material includes in the first place materials in the positive and negative electrode, but may also include certain components of the electrolyte.

4.1.1.1. Change of Volume

The active material changes its volume on charge and discharge. When the volume of the active material is increased, mechanical forces may be generated inside the battery that even may disrupt the battery casing, if no volume for expansion is provided. Reduction in volume, on the other hand, can cause contact problems between the electrodes and the separator that contains the immobilized electrolyte unless there is a mechanical component like a spring that provides pressing forces.

For example, during discharge of the alkaline air – zinc system, its zinc anode reacts with the oxygen of the air according to the overall reaction

$$Zn + 1/2\,O_2 \longrightarrow ZnO$$

The molar volume of ZnO is ca. 65 % larger than that of metallic zinc, and the battery construction must provide adequate space to allow for this change in volume, which is actually caused by the intake of atmospheric oxygen. Otherwise the battery would swell during discharge.

Other electrochemical systems exhibit a reduction in partial molar volume in consequence of discharge, like the monovalent silver oxide-zinc system. According to the overall reaction

$$Ag_2O + Zn \longrightarrow 2\,Ag + ZnO$$

its partial molar volume decreases by ca. 15 %. The CuO – Li system exhibits even a reduction in partial molar volume of ca. 42 %.

4.1.1.2. Change of Electrode Structure

The solubility of reaction products is a very important parameter for electrode reactions that occur via dissolution of the reactants, as in the case of lead, cadmium, zinc, or lithium electrodes. If the product or the discharge is highly soluble the electrode will – to a large extent – be dissolved during discharge and will lose its former structure. This leads to problems during recharge because the redeposition of the metal is favored where the concentration of the solution has its highest value. As a consequence, the structure of the electrode will be changed as demonstrated in the upper line of Figure 4.

Connected to the shape change is a further drawback of the high solubility, namely the tendency that during recharging the precipitated material forms dendrites that may penetrate the separator and reach the opposite electrode, thus gradually establishing a short circuit.

A typical example of this situation is the zinc electrode, which allows only limited discharge-charge cycles before it starts to establish electron conducting bridges between the electrodes. Zinc electrodes are therefore not used for commercial secondary batteries with the exception of the rechargeable alkaline zinc manganese dioxide battery (RAM) [28], [29], which is a within certain limits rechargeable battery of low initial cost, but limited cycle life.

The metallic lithium electrode is another case where cycling causes problems, in this case, however, not only due to shape change but also due to unwanted reactions with the electrolyte (see Sections 6.2 and 7.2.1).

Extremely low solubility of the reaction products leads to immediate precipitation and thus to the formation of an impermeable covering layer (lower line in Fig. 4). As a consequence, the discharge reaction comes to a halt as soon as the passivating layer is completed. To counteract such a passivation, the active material in corresponding technical electrodes, e.g., lead and cadmium electrodes, is used as a spongy structure that has a large surface area of the order of square meters per gram. A further advantage of such a porous structure is that the reaction products are precipitated immediately after their formation within the pores of the active material, close to the place of their origin, and the structure of the electrode remains nearly stable.

4.1.2. Nonactive Components

The split-up of the cell reaction into two electrode reactions as indicated in Figure 1 requires a number of nonactive components. They can be classified into conducting and nonconducting components.

4.1.2.1. Conducting Components

The current has to be collected from the active material and conducted to the terminals. Often the current conductor simultaneously acts as a support for the active material. In some systems the container of the cell is made of metal and often simultaneously acts as terminal. In Leclanché cells the container represents simultaneously the active material of the negative electrode.

When a number of electrodes are connected in parallel within the cell, corresponding connecting parts like pole bridges are required.

Additives, like carbon or metal powder, sometimes are required to improve the conductivity of the active material, especially in thick electrodes, and in electrode materials with low conductivity.

4.1.2.2. Nonconducting Components

Separators. The electronic separation of the two electrodes is another important condition. Any electronic contact between positive and negative electrodes constitutes a short circuit that discharges the cell concerned. On the other hand, the ionic current through the separator should be impeded as little as possible. In the early days of battery development, the widely spaced electrodes were only separated by rods of glass or rubber. In modern batteries, thin sheets of plastic materials, e.g., polyethylene, are used with a fine pore system in the micrometer range that provides a void volume of more than 80 %. Fiber felts of plastic or glass are also used as separators.

In batteries with an internal oxygen cycle, like valve-regulated lead – acid, sealed nickel – cadmium, or nickel – metal hydride batteries, the separator is important also for the

Figure 4. Effect of the solubility of the reaction products on electrode structure, when the discharging-charging mechanism occurs via the dissolved state

functioning of the oxygen cycle: the fine pores of the separator hold the electrolyte while the large pores stay open for fast oxygen transport through the gaseous phase.

In some alkaline batteries ion-conducting films like cellophane are used to prevent gas flow between the cells.

Polymer electrolytes can also be regarded as ion-conducting separators.

A semipermeable membrane that only allows the permeation of sodium ions is the β-alumina in sulfur – sodium or nickel chloride – sodium batteries (Sections 7.2 and 7.2.2.3).

Containers for rechargeable batteries are often made of nonconducting material. In lead – acid batteries it is a must to use glass, rubber, or plastics on account of the high cell voltage that would destroy all metals. Various types of plastic materials are used in the different systems. The advantage of a plastic container is that no insulation is required between adjacent cells. A general drawback of plastic materials is their permeability for gases, water vapor, and volatile substances. For this reason in sealed nickel – cadmium and nickel – metal hydride batteries metal has to be used instead of plastic material.

Seals. The seal of the terminals is a critical element. In *vented batteries* with liquid electrolyte it has to prevent creeping of the electrolyte which is especially observed for the negative terminal of batteries with alkaline electrolyte. With *sealed batteries*, the post seal has to prevent escape of electrolyte or its vapor, and the intake of oxygen from the surroundings. Special techniques have been developed for the different battery systems. Premium cells for space-craft applications but also lithium batteries for long service life often are equipped with metal – glass – metal seals that prevent any transport phenomena because of their glass body.

Vent plugs and valves are required, since a number of battery systems involve secondary reactions that generate gases which must escape. *Vents* as used for some rechargeable batteries are simple openings that allow gas flow in both directions, i.e., from outside into the battery and vice versa. The openings in such vent plugs are small to minimize water loss by evaporation. In modern batteries, such vents mostly are equipped with porous disks to prevent ignition sparks or flames from entering the cell and also the escape of acid or alkaline fumes from the cell.

Valves allow only the escape of gas and are used in most sealed batteries to prevent damage of the cell in the case of a too high internal pressure when the battery is abused, e.g., overcharged at a too high current rate (see Sections 7.1.1.12 and 7.1.2.1.11).

Rechargeable button cells in general have a *rupture vent* (breaking point) embossed in their metallic cell container that opens on a preset overpressure before the cell explodes. Safety features of this type are also employed in primary batteries but may be incorporated in their plastic seal instead.

4.2. Battery Parameters

The discharge/charge behavior of a battery depends on a number of parameters, like current, voltage, and temperature. These parameters have to be specified when such data are compared.

4.2.1. Voltage

In the case of reversible systems the *cell voltage* may be derived from the thermodynamic data of the cell reactions according to Equation (3.2). But often, this equilibrium voltage cannot exactly be measured (even not at open circuit), since secondary reactions cause a slight deviation (see Fig. 9). Then the *open cell voltage* (OCV) is actually measured, which, depending on the system, is often a function of the state of charge (SOC). Other systems, like some primary lithium systems, offer a rather high initial open circuit voltage, obviously due to the presence of higher valence oxides. This voltage collapses by several hundred millivolts on the slightest load and never recovers to its initial value.

The cell voltage under load, the *closed circuit voltage* (CCV) depends on the current, the state of charge, and on the cell's history, like, e.g., its lifetime or storage period.

A further term is the *nominal voltage* of a cell or battery that approximates the voltage of the concerned battery system. It is generally an open circuit voltage, rounded off to achieve a simple voltage designation, e.g., 3 V instead of 3.14 V or 2.86 V.

The *coup de fouet* or *initial voltage minimum* is a voltage minimum as indicated in Figure 5 at the beginning discharge of fully charged lead-acid batteries and is in the range of 20 mV per cell. It is caused by the positive electrode and can be ascribed to crystallization overvoltage [30]. Initial voltage minima are also known for lithium batteries. They are referred to as *initial voltage delay* and are caused by protecting layers being formed on the surface of the negative electrode during storage and being dissolved on discharge.

4.2.2. Capacity

The capacity of a battery is defined by international convention as the electrical charge in units of ampere hours that can be drawn from the battery. Thus, when the battery is discharged with a constant current, its capacity is given by the relation

$$C_{\mathrm{AH}} = i \cdot \Delta t \tag{4.1}$$

A more general definition would be

$$C_{\mathrm{AH}} = \int_0^t i\,(t) \cdot \mathrm{d}t \tag{4.2}$$

The discharge parameters that, besides the design of a battery, mainly influence the capacity are:

- Discharge current,
- Voltage limit that has to be specified and is known under various names: the final, the end point, the cut-off, or end-of-discharge voltage (EOD) and
- Temperature.

Further parameters that also influence the capacity, are the state of charge and the history of the battery, e.g., the preceding storage period. Any comparison of capacity data must always consider these parameters.

4.2.2.1. Secondary Batteries

Figure 5 shows as an example two typical discharge curves of a lead – acid battery. The upper curve represents a low-rate discharge, the lower curve a high-rate discharge.

The broken curve in Figure 5 represents the equilibrium voltage that for a lead – acid battery gradually decreases with progressing discharge on account of acid dilution. In other systems, where the electrolyte is not involved in the cell reaction, e.g., nickel – cadmium or nickel – metal hydride batteries, U^{o} remains approximately constant. The difference between the actual discharge curves and U^{o} is due to polarization according to Equation (3.7). This difference usually increases with progressing discharge because of a gradual increase of the internal resistance.

The *nominal* or *rated capacity* of a battery is specified by its manufacturer as the standard value that characterizes this battery. Usually it is specified for a constant-current discharge at

20 °C or at room temperature. For the various applications, nominal or rated capacities are often referred to different discharge duration, termed as C_{20}, C_{10}, or C_5, respectively, where the subscript denotes the discharge period in hours.

Figure 5. Typical low-rate discharge and high-rate discharge curves of a lead-acid battery and the main discharge parameters. The broken curve denotes the equilibrium or open circuit voltage.

Capacity ratings expressed as multiples of the nominal capacity were initially introduced for nickel – cadmium batteries. But it became common practice to address the current that characterizes charging or discharging of small lead – acid batteries and other rechargeable battery systems also in terms of capacity ratings. In this case the discharge current is written

$$i = m \cdot C_r \tag{4.3}$$

where i is the current in amperes; m is a number that indicates the multiple or fraction of C_r; C_r is the rated or nominal capacity in ampere hours, but expressed in amperes; and r is the discharge period in hours, the capacity is rated to. To indicate that the current is expressed as a multiple of the capacity, it is often written as "CA" or "C(A)". In this case "C" does not mean a capacity in ampere hours but a corresponding current in amperes. In regard to the dimensions, Equation (4.3) is not correct because it mixes quantities with units (i in A, C_r in Ah, m without unit). But in the battery field, this description of discharging and charging currents is well established and understood. It is even used in the standards of IEC/SC21A [31].

The factor m has no relation to discharge time: it is a pure number. For this reason, discharge rates in terms of multiples of the capacity cannot be converted into discharge durations. To evaluate the discharge duration, the discharge curves must be known.

The IEC Standard for lead – acid batteries [36], however, continues to use the corresponding currents, e.g., I_5, I_{10}, I_{20}, that describe the actual discharge duration.

The *depth of discharge* (DOD) is an important parameter in regard to the number of cycles that can be reached with rechargeable batteries. For lead – acid batteries, deep discharges that are continued beyond the recommended maximum DOD, can reduce the service life dramatically [14].

4.2.2.2. Primary Batteries

For primary batteries the term "capacity" as defined by Equations (4.1) or (4.2) is of course also applicable. Two discharge methods are in use:

1) Constant current discharge
2) Constant resistance discharge

Some test houses prefer method (1). By far predominant is, however, method (2) as is evident from manufacturer's technical handbooks. Method (2) prevails also in the IEC Standard for Primary Batteries [26], [33].

The discharge capacity of a battery decreases with increasing load as indicated in Figure 5 for a lead – acid battery. The same applies to primary batteries. The results of constant resistance discharges can be represented in a generalized form, shown in Figure 6: For a given cut-off voltage U_c, the discharge capacity $C(R)$ is plotted versus the discharge resistance R_d, measured in ohms.

Typical for this $C-R$ curve is the sharp increase in capacity C on increase of R_d in the range of low resistance values (high rate range), whereas in the low rate range (i.e., large R_d values) the discharge capacity C becomes finally independent of R_d. This is the battery's capacity plateau for which $dC/dR \approx 0$ is valid [32], i.e., $C \approx$ const. The $C-R$ plot is typical for all batteries. However, depending on the system's self-discharge which acts in parallel to the external discharge current, the plateau value of C_p may decrease again on further increasing R values. The plateau value $C_p \approx$ const is the battery's maximum capacity. $C_p \approx$ const implies

that within the plateau region also the discharge voltage U(plateau) is approximately constant. U(plateau) is independent of size and construction of the battery, and typical for its electrochemical system, because with such a low load, transport reactions are fast enough, and the battery's polarization is only determined by the charge-transfer resistance of its electrodes.

Figure 6. Schematic diagram of discharge capacity C versus discharge resistance R for a given end-point voltage and temperature. For the purpose of normalization $C(R)$ was divided by the plateau capacity C_{p}, that is reached at a sufficient high resistance. For the plateau $C(R)/C_{\mathrm{p}} = 1$ is valid.

Depending on manufacturer, the capacity of primary batteries may be given in terms of a service output duration, when simulating a certain application (e.g., transistor radio test, portable lighting test, toy test, etc.). The service output duration (in hours), as given for the individual application test, is proportional to the battery's capacity. The IEC Standard for Primary Batteries, which so far has proposed most of the existing application tests, quotes only "Minimum Average DurationValues" [26], [33] instead of capacities to describe battery performance. The "Minimum Average Duration Values" are exceeded significantly by at least 90 % of battery products available on the market.

4.2.3. Energy Content

In general form, the energy E that can be drawn from the battery is represented by the product

$$E = \int_0^t U(t) \cdot i(t) \cdot \mathrm{d}t \tag{4.4}$$

where E is the energy content in watt hours; U the voltage in volts; i the discharge current in amperes; and t the discharge period in hours. Direct measurements of the drawn energy are made with constant load (W), which means that the voltage decrease with proceeding discharge has to be compensated by an increase in current.

Usually, the battery is discharged with a constant current and the energy output is calculated by multiplying the measured Ah capacity by the discharge voltage. Characteristic voltages that are used for such an approximation are:

- *Initial discharge voltage*: voltage at the moment the load is applied.
- *Average discharge voltage* or *mean discharge voltage*: approximate average of the voltage during the whole discharge period (average discharge voltage × current = discharged energy).
- *Mid-point discharge voltage*: voltage after 50 % of the capacity has been discharged (≈ average voltage).

For constant resistance discharge as normally carried out for primary batteries, with R = const as resistive load, Equation (4.5) applies

$$E = \frac{1}{R} \int_0^t U(t)^2 \, \mathrm{d}t \tag{4.5}$$

Figure 7. Schematic discharge curve $U(R,t)$ versus discharge time t for a given load resistance R and end-point voltage U_{c}

Figure 7 is a schematic battery discharge curve with load resistance R for a given end-point voltage U_{c} at constant temperature ϑ. The average discharge voltage (and average discharge current) is given by the horizontal line that is defined by equal areas for t(A1 = A2). For a symmetrical curvature this average voltage equals the mid point discharge voltage for t_{D} = 50 %.

Specific Energy and Energy Density. For system comparison it has become common practice to relate the energy content of a given battery either to its volume or to its weight. The *weight-related energy* in watt hours per kilogram is the specific energy. (In the negligent use of such terms it is often also called energy density or gravimetric density, although a density should always be referred to a volume.) The specific energy is of special interest in the field of electric vehicles, since the weight of the battery determines the cruising range of the car. A typical value for a lead – acid traction battery is, e.g., 25 Wh/kg. For comparison: A modern lithium-ion battery offers ca. 125 Wh/kg.

The *volume-related energy density* is given in units of watt hours per liter or milliwatt hours per cubic centimeter. The energy density is of special interest for batteries designed to power portable equipment. In this application the size of the battery is in general more important than its weight. Present systems cover a range of 150 mWh/cm^3 (carbon – zinc) up to 1.2 Wh/cm^3 (alkaline air – zinc).

4.2.4. Internal Resistance and Power Output

The internal resistance of a battery is an important parameter since the power output is proportional to the reciprocal value of its internal resistance. Therefore it permits to differentiate between, e.g., high rate, medium rate, and low rate batteries, which again is of importance in judging the possibilities and limits of a battery's application. A general requirement is that the internal d.c.-resistance of the battery must be significantly below that of the appliance (1/10 and less), otherwise the voltage drop caused by the current demand of the appliance would limit the battery's service output duration too early.

The meaning of the term "internal resistance" has to be considered with some caution, because it is not a simple ohmic resistance and depends on the method that is used for its determination.

The *direct-current method* is frequently applied in battery practice. With this method, the terminal voltage is compared at various loads. The battery is loaded with the current i_1 for a few seconds and the cell or battery voltage U_1 results. Then the current is increased to the value i_2 and the battery voltage is reduced to the value U_2.

The internal resistance R_i can be calculated according to:

$$R_i = \frac{U_1 - U_2}{i_2 - i_1} = \frac{\Delta U}{\Delta i} \tag{4.6}$$

Equation (4.6) represents the usual method to determine an ohmic resistance. Batteries, however, do not represent an ohmic resistance. Their characteristic is nonlinear. This is illustrated in Figure 8, representing a schematic diagram of a quasi stationary current – voltage curve of a battery. According to Equation (4.6) the internal resistance R_i is given by the slope determined by

$$\Delta U/\Delta i = (U_1 - U_2)\,/\,(i_2 - i_1)$$

As illustrated in Figure 8, the value depends on the difference Δi. For infinitesimal values of Δi the internal resistance becomes $R_\mathrm{i} = \mathrm{d}U/\mathrm{d}i$, which is the tangent for a certain current. As is obvious from Figure 8, the slope, i.e., the internal resistance, changes with current i. The higher the current i, the flatter is the slope $\mathrm{d}U/\mathrm{d}i$, i.e., the smaller is the differential internal resistance, until finally the current approaches the limiting current i_lim. Then $\mathrm{d}U/\mathrm{d}i$ increases again. For $i = i_\mathrm{lim}$, the voltage U collapses due to a preceding rate determining process, and the internal resistance becomes infinitely high, $R \to \infty$. An example for such a behavior is the air – zinc system: With increasing current i the transport of oxygen, depending on the diffusion resistance for oxygen, becomes finally rate determining, i.e., the voltage under load collapses.

Figure 8. Quasi stationary current – voltage curve of a battery. Its internal resistance R_i is given by $\mathrm{d}U/\mathrm{d}i$ that often can be approximated by $\Delta U/\Delta i$. Such a curve naturally depends on the state of discharge

To achieve values for R_i that are relevant to practical applications, the currents i_1 and i_2 usually are specified and adapted to different battery types (examples, e.g., in [14, p. 90]).

The internal resistance R_i, determined according to Equation (4.6), comprises ohmic resistance within the electrodes and the electrolyte as well as overvoltage at the phase boundaries between the electrodes and their electrolyte. Equation (4.6) implies that the overvoltage is rather small compared to the ohmic voltage drop. For batteries with aqueous electrolyte this is true only for the discharge, not during charging because of the high overvoltage of the gassing reactions.

The *short-circuit current* is of interest especially for larger stationary batteries, since it stands for the maximum current that could be supplied by the battery for a short period of time. Its value helps in estimating the size of fuses that might operate with the battery. The short-circuit current is determined according to Equation (4.6) by extrapolating the resulting line to the voltage zero. The short-circuit current represents a dynamic parameter that decreases quickly with proceeding discharge. Published values are always referred to the fully charged battery.

The *a.c. internal resistance* of a battery is a complex parameter and difficult to interpret, since the a.c. behavior of a battery can only be approximated by an equivalent circuit of many components. In the 1990s, the ohmic part of the impedance gained importance as a possibility to check the situation of valve-regulated lead – acid batteries that otherwise could be determined only by discharging. The impedance is mostly measured at a frequency of 1000 Hz. At such a high frequency it does not give any information on the battery's electrochemistry but only on its ohmic components, including the electrolyte. The resulting values are used for comparison, to detect faulty cells within a string.

Specific Power Output. A performance feature which is of special interest in the field of primary batteries is the battery's specific power output $P*$ (see Eq. 4.7). It depends basically on the following five parameters:

1) Battery size
2) System
3) Internal battery construction
4) State of charge/discharge
5) Temperature

It is evident that the power output of a battery for given parameters 2 – 5 increases with size and vice versa. The change in size, however, does not mean that the battery may finally become a high rate or low rate battery, because of its increased or reduced power output. The terms *high rate* and *low rate* are special cases of the specific power output, which is obtained when the battery's power output in watts is divided by its envelope volume V as defined by the Equation (4.7).

$$P^* = \frac{U^2\,(C/2)}{R\,(C/2) \times V} \tag{4.7}$$

The value for $P*$ depends on the experimental conditions under which it is determined. The range of $P*$ values as quoted below for primary batteries was determined by the following schedule [32]:

1) Discharge fresh battery by 50 % through R_s that would yield 98 % (or above) of plateau capacity $C_p : C(R_1) \geq 0.98 \times C_p$
2) Apply discharge resistor $R(C/2) = R(0.5)$ that yields 50 % of C_p (cf. Fig. 6) and read voltage U after 3 s
3) Calculate $P*$-value according to Equation (4.7)

The approximate range as covered by present primary battery systems for consumer application is 3 mW/cm^3 up to 400 mW/cm^3. The highest values were verified for cylindrical batteries of the MnO_2 – Li system with an organic electrolyte. The large range of these values is partly caused by the different electrochemical systems, but mainly by differences in their internal construction. The first value (3 mW/cm^3) is a low rate value, being typical for a simple "bobbin" type electrode construction (cf. Section 6). The second value (400 mW/cm^3) is typical for a high rate battery construction, using spirally wound electrodes.

Present specific power outputs may be either determined individually or they may be grouped into ranges [34] like

1. Low rate: $P* < 5\,\mathrm{mW/cm^3}$
2. Medium low rate: $5\,\mathrm{mW/cm^3} \leq P* < 20\,\mathrm{mW/cm^3}$
3. Medium rate: $20\,\mathrm{mW/cm^3} \leq P* < 80\,\mathrm{mW/cm^3}$
4. Medium high rate: $80\,\mathrm{mW/cm^3} \leq P* < 320\,\mathrm{mW/cm^3}$
5. High rate: $P* \geq 320\,\mathrm{mW/cm^3}$

Under the conditions quoted above, cylindrical batteries, employing spirally wound electrodes, belong exclusively to the high rate range, i.e., group 5. Groups 1 to 4 serve only to differentiate between lower rate systems, which include most of the primary batteries and some of the rechargeable systems.

4.2.5. Charge Parameters

The charging process basically represents the reversal of the discharge. Theoretically it occurs as soon as the voltage of the cell attains a value just above the equilibrium voltage U^{o}. In practice, however, higher voltages have to be applied to achieve full charge within a desired period. With increased cell voltage, however, parasitic reactions, such as water decomposition in the case of aqueous electrolytes, may gain more significance. Charging methods therefore always have to compromise between charging at a rather low rate with high efficiency and faster but less effective charging. Furthermore, fast charging methods must be controlled, since they may cause thermal problems, and for a number of battery systems, like lithium-ion cells, overcharging must strictly be avoided since it would cause irreversible reactions.

As a consequence, a great number of different charging methods have been developed, adapted to the type of battery and to the requirements of the application.

The charging process is mainly influenced by three parameters:

Charging current,
Charging voltage, and
Temperature of the battery

Charge acceptance or *charge current efficiency* describes the share of the current, that actually is "accepted" by the battery and can be retrieved by subsequent discharging. It is determined by the balance between the kinetic parameters of the charging reaction and the secondary processes that simultaneously may occur.

4.2.6. Self-Discharge

Self-discharge means gradual loss of charge in the positive and/or negative electrode, when the battery is stored at open-circuit. One reason can be the gradual decrease of the oxidation state in the positive electrode, e.g., the loss of oxygen in nickel hydroxide electrodes.

Figure 9. Mixed potential between discharge of the lead electrode and hydrogen evolution with the result of self-discharge. The dashed curve represents reduced hydrogen overvoltage
U_{M} = mixed potential; i_1, i_2 = rate of self-discharge

4.2.6.1. Mixed Potential

Secondary reactions can also cause self-discharge when these reactions are thermodynamically possible at the equilibrium potential and cause discharge of the concerned electrode. Then the secondary reaction and the discharge reaction form a mixed potential as shown in Fig. 9. The two electrochemical reactions compensate each other, and gradual discharge is the consequence (cf. Section 7.1.1.3).

The fairly steep current – voltage curve pointing upwards represents the discharge of the lead electrode. The fast rise of this curve indicates the low overvoltage that characterizes this reaction. It means that high discharge rates can be achieved at low overvoltage or polarization values. The high overvoltage, characteristic of the hydrogen-evolution reaction, is expressed by

[2]
the gradual rise of the corresponding flat current curve. At open-circuit voltage, discharge reaction and hydrogen evolution have to balance each other, because no external current flows through the electrode. The result of this balance is a mixed potential, U_M in Figure 9. As for an equilibrium potential, no external current appears. But the mixed potential is not an equilibrium potential, because two different reactions occur, and gradual discharge of the negative electrode is the result.

The position of the mixed potential is largely determined by the faster one of the two reactions, while the rate of the reaction, the self-discharge in this example, is determined by the slower reaction. This is illustrated by comparison of the continuous and broken curves in Figure 9. The continuous curve represents a fairly high hydrogen overvoltage; the broken curve depicts the case when hydrogen can be evolved more easily. The position of U_M is only slightly changed between the two examples, but the rate of the self-discharge, the current i_2, grows to a multiple of i_1 in the second case.

4.2.6.2. Further Self-Discharge Mechanisms

Self-discharge can also be caused by oxidizable or reducible substances in the electrolyte, when they reach the positive or negative electrode, respectively. Oxidation of the critical substance means a corresponding reduction of the active material within the electrode and vice versa.

Such an effect is called a "shuttle" when the oxidized and reduced form of the critical substance remain dissolved and alternatively are oxidized and reduced at the positive and the negative electrode, respectively. In nickel – cadmium batteries, for example, this can be caused by iron ions which are reduced at the negative electrode according to

$$Fe^{3+} + e^- \longrightarrow Fe^{2+}$$

The Fe^{2+} ions migrate to the positive electrode, where they are oxidized by the reverse reaction. The process is repeated, when the so formed Fe^{3+} ions again reach the negative electrode. In this way both electrodes are gradually discharged (cf. the "nitrate shuttle"in Section 7.1.2.1.7).

The formation of electron conducting bridges is another mechanism that may establish a self-discharge. An example is the formation of ZnO dendrites penetrating the separator system and getting in touch with the cathode, consisting, e.g., of Ag_2O. The cathode material itself, if soluble to a certain extent like Ag_2O, may also lead to the formation of electron-conducting Ag bridges if reduced by cell components, like, e.g., an unsuitable separator [35].

4.2.6.3. Apparent Self-Discharge

After prolonged storage of primary cells, their increased internal resistance is often misinterpreted as self-discharge. The reason for the increase in internal resistance has nothing to do with chemical or electrochemical self-discharge, but only with mass transfer. If, e.g., the cathode has void pores it will soak-up electrolyt during storage from the region between anode and cathode, thus reducing the battery's load capability. Lithium batteries with a plastic seal will pick up humidity during storage and loose volatile electrolyte components by permeation. The air – zinc battery will loose water by evaporation after activation, if stored in an environment with lower humidity, which may also lead to a considerable increase in internal resistance.

The increased internal resistance reduces the voltage under load, and the end-of-discharge voltage is reached earlier compared to a fresh battery. Thus the delivered capacity is reduced although the electrodes are still fully charged, i.e., the battery's full capacity may still be obtained at a reduced load.

4.2.6.4. Capacity Loss During Storage

For all the reasons given above, a battery loses capacity during storage. The loss of capacity depends on system, construction, and storage conditions, such as temperature. Therefore a wide region of self-discharge ranges is observed. In primary batteries with lithium electrodes, a protecting layer is formed at the electrode surface and extremely low self-discharge results. As a rule of thumb, for a given battery system the self-discharge rate correlates roughly with its

specific power output, i.e., the higher its specific power output, the higher the self-discharge. The reason is that both, self-discharge and power output, correlate with the electrode surface, i.e., an increased electrode surface means both, an increased power output and an increased self-discharge, especially at reduced electrode distances.

Practical values for *primary batteries* at ambient temperature, that also include the apparent self-discharge (see Section 4.2.6.3), are in the range of 0.5 % (and less) to 20 % per year. The low value applies, e.g., to lithium batteries with a high quality seal. The 20 % value is considered to be a maximum value for low cost carbon – zinc batteries, which is, however, mostly determined by the apparent self-discharge (see Section 4.2.6.3). The true chemical and/or electrochemical self-discharge is much smaller, unless low quality active materials are employed.

Also *secondary battery systems* exhibit a broad range of different rates of self-discharge. Their values, however are based on a one-month period in contrast to primary systems (one-year period). Depending on system and construction, typical values vary between 2 and 30 % at ambient temperature. For the lead – acid system the values vary between 2 and 20 % depending on antimony content and age. The lithium-ion system offers about 5 % per month. Values in the range of 20 to 30 % per month are observed for the nickel – cadmium and the nickel – metal hydride system.

Instead of the term capacity loss ΔC_s the term capacity retention ΔC_R is also in use. The capacity retention is defined by

$$\Delta C_R / C = 1 - \Delta C_S / C$$

C being the initial capacity of the fresh (and charged) battery.

5. Classification of Battery Systems

Both primary and secondary systems may be further classified by characteristics that allow for a systematic subclassification of the various battery systems. One guiding principle is the classification by electrolyte. Another possibility of battery classification is to base it on battery construction.

Choice of Battery Classification. For the classification of battery systems, preference was given to the classification by electrolyte according to chapter 5.1 with 5.2 as sub-system whenever appropriate.

5.1. Classification by Electrolyte

There are two groups of electrolyte, i.e., aqueous and nonaqueous electrolytes, any battery system may be allocated to:

1) Group 1: Battery systems employing an *aqueous electrolyte* may be divided up into following subgroups
   1) Strong acidic electrolyte (*lead – acid batteries*)
   2) Weak acidic electrolyte (e.g., *Leclanché batteries*)
   3) Neutral electrolyte (e.g., *water activated systems*)
   4) Alkaline electrolyte (e.g., *nickel–cadmium*, *alkaline manganese dioxide – zinc*). The prevailing electrolyte is potassium hydroxide (KOH).
2) Group 2: Battery systems employing a *nonaqueous electrolyte* may be divided up into following subgroups
   1) Organic electrolyte (e.g., *manganese dioxide – lithium, lithium-ion*)
   2) Electrolytes with soluble cathode (e.g., *thionyl chloride*)
   3) Polymer electrolyte (e.g., *vanadium pentoxide – lithium*)
   4) Solid electrolyte (e.g., *iodine – lithium, sulfur – sodium*)

5.2. Classification by Construction

Several constructional principles exist that are common for a great number of battery systems. This concerns the outward appearance as well as internal design features.

5.2.1. External Construction

The external constructional principles are represented by three groups:

Prismatic cells (e.g., Figs. 69, 77, and 86), are characterized by the dimensions length, width, and height. This design is mainly used for larger secondary cells with electrodes in form of plates. But also small prismatic cells exist and even miniaturized ones like those used in modern credit cards. Very flat cell constructions (e.g., below 1 mm in thickness) may be even flexible. One advantage of the prismatic design is the possibility to efficiently use the rectangular volume (cf., e.g., Figs. 77 and 87).

Cylindrical cells (e.g., Figs. 70, 88) are characterized by dimensions diameter d and height h for $h > d$. They are the domain of primary batteries, sealed nickel – cadmium, nickel – metal hydride, and lithium-ion batteries. To some extent they are also used for valve-regulated lead – acid batteries.

Button cells (e.g., Fig. 85) are characterized by dimensions diameter d and height h for $h \leq d$. They are in widespread use as primary batteries, sealed nickel – cadmium, nickel – metal hydride, and lithium batteries.

Battery Packs and Smart Batteries. For many applications, like tools, camcorders, mobile and cordless telephones, rechargeable batteries are assembled to *battery packs*, also called *power packs* that combine a number of cells within a common housing. The cells in such a pack are often selected to ensure their uniform capacity (see Section 7.1.2.1.10).

Smart batteries or "intelligent" batteries have an incorporated controlling system, based on a processor that provides information to the host device in regard to capacity and aging of the battery.

Battery packs and smart batteries are often characterized by different multi-contact and special mechanical fit-in arrangements, i.e., they often fit only one specific device they are made for.

5.2.2. Internal Construction

The internal constructional features are manifold, at least when they are considered in detail. Some of these features will be described in Chapters 6 and 7. The internal construction is mainly determined by the design of the battery's electrodes. Basically there are three different electrode designs:

1) *Pressed electrodes with direct contact to the container wall*. Examples are the disc electrodes in button cells (Fig. 85) and the manganese dioxide cathode rings of the alkaline manganese dioxide-zinc cell. (Fig. 21).
2) *Electrode plates* that usually are connected in parallel to enlarge the surface area and form plate groups (Figs. 68, 86). The thickness of the plates reaches from more than 1 cm to fractions of a millimeter.
3) *Spirally wound electrodes* are often used in cylindrical cells (Figs. 70, 88). Usually one positive and one negative electrode with the separator in between are wound together and form the "electrode group".

Safe-Guarding Devices. For the safe operation of batteries safe-guarding devices are integrated. Valves, vent plugs, and rupture vents as already discussed in Section 4.1.2.2, are *mechanical devices*. They are described in detail in Sections 7.1.1.12 and 7.1.2.1.11.

Furthermore *nonmechanical* safe guarding devices are employed for battery packs, and to some extent also for single cells. These may be thermal fuses, or devices that increase the internal resistance when a specified temperature is exceeded, e.g., PTC devices as in Figure 32. A safety switch, controlled by the current, is shown in Figure 10. The cell temperature is often used for charge control (see Section 7.1.2.1.12). Corresponding temperature sensors are installed in the charging device or already in the battery pack. The processor of smart batteries also controls proper charging, and prevents overdischarge.

a) Al burst disk; b) Al connection between cell cover and positive electrode

6. Primary Batteries, Systems, and Application

The system classification of primary batteries is carried out according to Section 5.1 (classification by electrolyte), with the exception of Section 6.3, dealing with reserve batteries, which form a group of their own.

The first group of systems to be presented employ aqueous electrolytes. This group is governed by the carbon – zinc systems. Systems with aqueous electrolyte may be roughly subdivided by the pH value of their electrolyte. The first subgroup employs weak acid electrolytes having an pH value in the range of $2 < pH < 4$. This group is also dominated by the "carbon – zinc" system. The second subgroup employs a nearly neutral electrolyte like seawater and is governed by magnesium systems. The third subgroup, finally, uses strong alkaline electrolytes, predominantly KOH ($pH > 14$) and is again dominated by zinc systems.

The second group of systems employ nonaqueous electrolytes. They are governed by lithium systems using either an organic, inorganic, or solid electrolyte and are subdivided accordingly.

In this article only systems and batteries will be addressed, that have received commercial significance. Systems and batteries for very specific applications will not be covered, apart from a few exceptions. Reference is made instead to the existing literature, e.g., [37].

6.1. Systems Employing an Aqueous Electrolyte

6.1.1. Batteries with Weak Acid Electrolyte

6.1.1.1. Carbon – Zinc Systems

6.1.1.1.1. General

The system's popular name is carbon – zinc, its correct name would be the "manganese dioxide – zinc system with weak acid electrolyte".

Normally a battery system is named after its active materials. In the case of carbon – zinc, however, reference is made actually to its current collectors, which is carbon for its positive and zinc for its negative terminal. Zinc is simultaneously the active material of the negative electrode. For cylindrical batteries, zinc is also part of the battery construction, i.e., it is the can of the battery. The multifunction of the zinc is one of the reasons why the system can be produced at rather low costs and which in turn is the reason for its widespread use. The system has been standardized by the IEC [26], [35] but did not receive a system letter of its own in contrast to all other standardized systems.

There are two variants of carbon – zinc systems. Both variants exist in different grades, depending on the quality of the active material and the type of construction employed. The first variant uses predominantly ammonium chloride as electrolyte and is therefore named the "ammonium chloride" system. Since it was pioneered by George Lechlanché it is also known as "Leclanché" system. The second variant uses predominantly zinc chloride as electrolyte and is therefore called the ″zinc chloride″ system. The literature on this subject is abundant [38–40].

The alkaline version of the manganese dioxide – zinc battery surpasses the carbon – zinc systems in performance by far, however, at higher costs. This system will be dealt with in Section 6.1.3.1.

6.1.1.1.2. Electrochemistry

Both variants of the carbon – zinc system employ manganese dioxide as cathode material (positive electrode) and zinc as anode material (negative electrode). The reaction mechanisms of these systems are rather complex. Under light discharge conditions the following reactions occur:

"Ammonium Chloride" or Leclanché System. The electrochemical reaction of the negative electrode is given by Equation (6.1)

$$Zn + 2\,Cl^- \longrightarrow ZnCl_2 + 2\,e^- \tag{6.1}$$

The electrochemical reaction of the positive electrode is described by Equation (6.2)

$$2\,MnO_2 + 2\,NH_4Cl + 2\,e^- \longrightarrow 2\,MnOOH + 2\,NH_3 + 2\,Cl^- \tag{6.2}$$

Reactions (6.1) and (6.2) are followed by a precipitation of zinc diammine chloride (Eq. 6.3)

$$ZnCl_2 + 2\,NH_3 \longrightarrow [Zn(NH_3)_2]Cl_2 \tag{6.3}$$

The overall reaction is

$$2\,MnO_2 + Zn + 2\,NH_4Cl \longrightarrow 2\,MnOOH + [Zn(NH_3)_2]Cl_2 \tag{6.4}$$

and will be discussed below.

Zinc Chloride Battery. The electrochemical reaction of the negative electrode is given by Equation (6.5)

$$Zn + 2\,Cl^- \longrightarrow ZnCl_2 + 2\,e^- \tag{6.5}$$

The reaction of the positive electrode is described by Equation (6.6):

$$8\,MnO_2 + 4\,ZnCl_2 + 4\,H_2O + 8\,e^- \longrightarrow 8\,MnOOH + 4\,ZnO + 8\,Cl^- \tag{6.6}$$

Reactions (6.5) and (6.6) are followed by a precipitation of zinc oxychloride. At high current densities it is preferably generated in the anode compartment.

$$4\,Zn^{2+} + ZnCl_2 + 9\,H_2O \longrightarrow ZnCl_2 \cdot 4\,ZnO \cdot 5\,H_2O + 8\,H^+ \tag{6.7}$$

The overall reaction is

$$8\,MnO_2 + 4\,Zn + ZnCl_2 + 9\,H_2O \longrightarrow 8\,MnOOH + ZnCl_2 \cdot 4\,ZnO \cdot 5\,H_2O \tag{6.8}$$

System Comparison. One of the outstanding features of the zinc chloride system in comparison to the ammonium chloride system is its superior resistance to leakage, which follows from Equation (6.4) in comparison to Equation (6.8): In contrast to the zinc chloride system the ammonium chloride system does neither use up water in the course of a reaction, nor does it generate water, whereas the zinc chloride system reacts with water molecules by producing zinc oxychloride.

Under light discharge conditions with endpoint voltages of $U \geq 0.75\,V$ the ammonium chloride system is also unlikely to leak.

The difference in leakage behavior becomes, however, evident under the condition of prolonged discharge, i.e., discharge voltages of 0.7 V and below. Under this condition the following reaction occurs in the ammonium chloride system:

$$Zn + 6\,MnOOH \longrightarrow 2\,Mn_3O_4 + ZnO + 3\,H_2O \tag{6.9}$$

This reaction involves generation of water and is inevitably followed by electrolyte leakage. The leakage is also favored by an internal pressure built-up and the perforation of the zinc can that most likely occurs under these conditions. This is in contrast to the zinc chloride system, which continues to use up water by producing complex compounds similar to zinc oxychloride (see Eq. 6.8) and which also leads to a reduction in electrolyte volume, thus effectively reducing the problem of electrolyte leakage.

Another outstanding feature of the zinc chloride system is the property of its precipitate (Eq. 6.7) in comparison to the precipitate formed by the ammonium chloride system (Eq. 6.3). The precipitate of zinc diammine chloride is much more dense than the microporous zinc oxychloride. This difference becomes more pronounced at higher current densities. This means that the zinc diammine chloride precipitate not only represents a severe diffusion barrier leading to marked diffusion polarization for all diffusing species but also to an increase of the system's ohmic resistance. For the zinc chloride system these negative effects are much less pronounced, i.e., it offers a higher load capability.

Another advantage of the zinc chloride system is the larger volume of electrolyte being employed (approx. 15 % more). Due to a special mixing process for the positive mass (MnO_2, acetylene black, and $ZnCl_2$ electrolyte) pores are established, being filled with electrolyte. These pores permit approx. 36 % higher transport rates of species according to Equation (6.6), than those of the ammonium chloride system according to Equation (6.2). At higher discharge currents this also means lesser concentration polarization within the cathode of the zinc chloride system in comparison to the ammonium chloride system. These advantages of the zinc chloride system over the ammonium chloride system disappear for low and/or intermittent current densities.

A disadvantage of the zinc chloride system in comparison to the ammonium chloride system is its storage behavior. When employing the same active materials, swelling agents and seal, etc., the zinc chloride system tends to dry out faster than the ammonium chloride system. This, however, can be overcome by a proper choice of swelling agents, nonporous carbon as current collector, an increased amount of carbon black, high quality active materials, and a hermetic seal. These measures, however, mean higher costs in comparison to the ammonium chloride system.

Figure 11. Open circuit voltage of R20 sized batteries containing electrodeposited MnO_2 in the IEC radio test [45] o R20 ("carbon – zinc") • LR20 (alkaline electrolyte)

6.1.1.1.3. System-Immanent Properties

System-immanent properties are directly correlated to the electrochemical reaction occurring in the system and to transport phenomena. According to Chapter 3, the open circuit voltage U^o may be calculated from the thermodynamic data of the cell reaction. This is also true for the carbon – zinc system. The MnO_2 used as cathode material, however, has the peculiarity that its open circuit potential U^o depends not only on the MnO_2 modification employed [The more important modifications are: natural manganese dioxide (NMD), lowest quality; activated manganese dioxide (AMD); chemically synthesized manganese dioxide (CMD), and electrodeposited manganese dioxide (EMD), highest quality)] but also on the degree of electrochemical reduction [41–43].

In a buffered ammonium chloride solution the open circuit voltage U^o of α-MnO_x covers a range of $1.6\,V > U^o \geq 1.05\,V$, for $1.98 > x \geq 1.87$ [44], indicating a homogeneous phase being followed by a heterogeneous phase for $1.87 > x > 1.39$ while exhibiting a constant open circuit value U^o of approx. 1.05 V.

A relevant dependence of the U^o-value on discharge is also observed for EMD in an alkaline electrolyte [45]. Experimental values obtained when applying an IEC radio test to R20 and LR20 batteries (IEC application test: 10 Ω; 4 h/d) are shown in Figure 11, indicating a homogeneous reaction between MnO_2 and $MnO_{1.5}$.

Another system-immanent property has to do with the zinc and the fact that its potential is − 0.42 V versus the hydrogen potential in the same electrolyte, i.e., Reaction (6.10) proceeds, if not inhibited.

$$Zn + H_2O \longrightarrow ZnO + H_2 \tag{6.10}$$

Indeed, this reaction, characterized by a dissolution of zinc and the generation of hydrogen, or variants of it have caused considerable problems in the past. These problems finally were solved by the addition of mercurous chloride, which forms an amalgam with zinc, leading thus to an inhibition of Reaction (6.10). This treatment led to a considerable improvement of the system's storage behavior (reduction of internal self-discharge, elimination of problems connected with internal H_2 pressure and can corrosion). However, because of the environmental problems, mercury had to be eliminated or replaced. At present nearly all battery manufacturers succeeded to replace zinc amalgam by other environmentally benign zinc alloys.

The system's specific energy (mWh/g) and the system's energy density (mWh/cm^3) are further system-immanent properties. When assuming an average discharge voltage of 1.3 V the following theoretical values may be derived under simplified conditions (one electron step reaction according to Reaction 6.8):

Specific energy: 222 mWh/g
Energy density: 727 mWh/cm^3

Figure 12. Continuous and discontinuous discharge through 3.9 Ω
A) Ammonium chloride R14S battery, endpoint voltage 0.9 V; B) Zinc chloride R14P battery, endpoint voltage 0.9 V

Values obtained under experimental conditions, however, are significantly below. When discharging a modern premium grade R20 zinc chloride battery at low current (e.g., at 0.15 mA/cm^3, endpoint voltage 0.9 V) the following experimental discharge values may be verified:

Specific energy: 120 mWh/g
Energy density: 200 mWh/cm^3

Low-cost carbon – zinc batteries, using NMD, exhibit an inferior performance. Their values may even be below 70 mWh/g and 120 mWh/cm^3.

The difference between theoretical and experimental values not only depends on the quality of the manganese dioxide and the porosity of the cathode used in the battery, but also on weight and volume of the excess zinc necessary to produce the can, and inactive materials such as separator, carbon rod, graphite, carbon black, labeled metal jacket plus insulation and contact arrangements.

For increased discharge currents (2 mA/cm^3 and above) further system-immanent properties become noticeable, which are governed by electrode kinetics and transport phenomena. Under increased discharge currents a diffusion barrier builds up (see Section 6.1.1.1.2). The formation of a diffusion barrier is a time dependent process that leads to an increasing diffusion polarization, which is accompanied by an increasing voltage drop under load (CCV). On current interruption the voltage recovers because the diffusion barrier regresses. Figure 12 illustrates the discharge of two ammonium chloride batteries type R14S. One discharge was carried out discontinuously according to an IEC portable lighting test, i.e., 3.9 Ω, 4 min/h, 8 h/d. The other R14S battery was discharged continuously through a 3.9 Ω resistance. The continuous test yields only 27 % of the capacity which the discontinuous test provides.

This is the fundamental reason why carbon – zinc batteries perform better under intermittent load conditions. This is especially true for the ammonium chloride system. The zinc chloride system offers a higher load capability and is less time dependent in its performance (see Fig. 12 B). Figure 12 B illustrates the discharge results of two zinc chloride batteries type R14P, which were discharged under identical conditions. The result for the zinc chloride system is that under continuous discharge conditions 58% of the capacity is available, instead of only 27 % for the ammonium chloride system (Fig. 12 A).

For low current demands the advantage of the zinc chloride system over the ammonium chloride system diminishes, i.e., both provide the same capacity. In those cases the cheaper ammonium chloride system may be the better choice.

6.1.1.1.4. Batteries and Their Applications

The final property of an electrochemical system is given by both, its system-immanent properties (including the choice of materials) and its battery design (the design includes battery construction and size).

According to Section 5.2 three constructions have been established by time: Cylindrical, button, and prismatic cells.

Carbon – zinc batteries are made only in cylindrical and prismatic shapes with a variety of terminal arrangements. They are manufactured with different internal constructions. The more important ones are described below.

Figure 13. Cross-section of an ammonium chloride (A) and a zinc chloride cylindrical battery (B)

Cylindrical batteries are characterized by diameter d and height h, with $d < h$. The cylindrical carbon – zinc battery is made in two basically different internal constructions. The construction according to Figure 13 A is predominantly used for low cost ammonium chloride batteries, whereas the construction according to Figure 13 B is predominantly used for the more expensive zinc chloride battery, which needs a better seal (see Section 6.1.1.1.2).

For both carbon – zinc systems the following IEC battery sizes are available on the market (in sequence of increasing volume, cf. Chap. 9):

R03 (AAA), R1 (N), R6 (AA), R14 (C) and R20 (D) [The designations AAA, N, AA, C and D are no longer valid ANSI (American National Standard Institute) designations for cylindrical ammonium chloride batteries with natural manganese dioxide. They are unofficially still in use, however, only to designate battery sizes].

For batteries R6, R14 and R20 three performance variants are standardized, characterized by suffices S (standard), C (high capacity), and P (high power) [58], [33].

In general suffix S, e.g., R6S, R14S, R20S designates ammonium chloride batteries whereas suffix P designates in general zinc chloride batteries, e.g., R6P, R14P and R20P. Thus suffix "S" batteries are of a lower performance than suffix "P" batteries, whereas suffix "C" batteries offer a medium performance but at a higher capacity. Since the use of IEC designations is voluntary, not all manufacturers follow the IEC proposal to designate their performance variants by suffices S, C, and P.

The most important battery size by production volume is presently the R6 (AA) battery. The discharge behavior of both carbon – zinc systems is illustrated in Figure 14 A and B. Figure 14 A shows the voltage-time transient of an IEC transistor radio test, which is a discontinuous test with a 43 Ω load, 4 h/d. Figure 14 B is the voltage – time transient of an IEC pulse test (simulating a photo flash), which is a discontinuous test with a 1.8 Ω load, 15 s on and 45 s off, 24 h/d and which represents a much higher discharge rate.

Figure 14 A demonstrates a discontinuous low rate discharge. Under this condition the ammonium chloride system offers practically the same performance as the zinc chloride system. Under pulse test conditions, however, the R6P battery (zinc chloride) is superior to the R6S battery (ammonium chloride) by about 42 %, see Figure 14 B. If compared, however, to a LR6 battery (see Section 6.1.3.1), the R6S and the R6P battery are by far inferior. This is illustrated by the discharge result of a LR6 battery, as incorporated into Figure 14 B. With an endpoint voltage

Figure 14. R6P and R6S batteries
A) Transistor radio test; B) 1.8 Ω pulse test

of 0.9 V it provides nearly four times more capacity than the R6P battery.

For an interpretation of the results of Figure 14 see the explanations given in Sections 6.1.1.1.2 and 6.1.1.1.3. The statements are valid independent of battery size. The applications for the carbon – zinc cylindrical batteries are manifold and change with changing technology. Typical applications are listed in Table 1.

Table 1. Applications of 1.5 V cylindrical carbon – zinc batteries according to IEC

Applications	R03	R1	R6	R14	R20
Portable lighting	x	x		x	x
Personal cassette players	x		x		
Tape recorder				x	x
Transistor radios	x		x	x	x
Pulse test (photo flash)	x		x		
Hearing aids		x			
Paging		x			
Motor/toy			x	x	x

Prismatic batteries are characterized by length, width, and height. Carbon – zinc prismatic batteries are mostly multicell batteries, i.e., they have normally at least two cells connected in series and therefore open circuit voltages of 3 V and above, e.g., 30 V. Batteries of this type, however, are more and more disappearing from the market with a few exceptions, like the 9 V battery according to IEC designation 6F22. It has six flat cells (IEC size F22) connected in series. The external and internal construction of the battery is shown in Figure 15.

The main applications of this battery are:

- Remote control,
- Smoke detectors,
- Electrical multi-meters (small transportable, multifunction instruments, e.g., for measurement of current, voltage, or resistance),
- Toys, and
- Transistor radios.

The 6F22 9 V carbon – zinc battery exists also as alkaline version, having the IEC designation 6LR61, (see Section 6.1.3.1). It surpasses all carbon – zinc versions in performance, but is also more expensive.

Figure 15. Construction of a 9 V IEC type 6F22 carbon – zinc battery

Another well known prismatic battery construction is the 4.5 V battery according to IEC designation 3R12. It contains three cylindrical cells in series (IEC size R12). Its external construction is illustrated in Figure 16. The main ap-

plications of this battery are in portable lighting and transistor radios.

Figure 16. External construction of the 4.5 V IEC type 3R12 carbon – zinc battery

According to IEC this battery exists in three performance variants designated by suffices S (standard), C (high capacity) and P (high power). The 3R12 4.5 V carbon – zinc battery exists also as alkaline version, having the IEC designation 3LR12, (see Section 6.1.3.1). It surpasses all carbon – zinc versions in performance, but again it is offered at a higher price.

The specific energy and the energy density of multicell batteries are below corresponding values of single cell batteries like, e.g., the R20 cylindrical battery. The reason for this is the higher percentage of inactive materials and volume being unavoidable for multicell batteries. For a 6F22 battery, e.g., the values are approx. 30 % below those quoted in Section 6.1.1.1.3.

Battery Packs. A unique battery is the four cell flatpack 6 V battery, manufactured by the Polaroid Corporation [46] and being integrated into a 10 pictures film-pack. This concept ensures that each film-pack has always a fresh battery (film transport, flashlight, shutter operation, etc.). The pack basically consists of a carbon – zinc multicell battery with zinc chloride as electrolyte, having a geometric electrode area of approx. 5.1 by 5.1 cm. At a discharge current of 1 A it offers a capacity of approx. 100 mAh, at a 1 mA discharge rate the capacity rises to about 250 mAh. The exploded view in Figure 17 represents a single cell [47].

Figure 17. Exploded view of a single cell from a Polaroid P-80 battery pack

More information on carbon – zinc batteries (performance and applications) is given in manufacturer's data sheets, brochures and technical handbooks and in the IEC-Standard Public. 86 [26], [33].

6.1.1.1.5. Prospects

By now the carbon – zinc system has been on the market for about 100 years and will continue to exist. There is no reason to assume that this system will disappear in the foreseeable future. The worldwide annual production volume is estimated to be 18×10^9 carbon – zinc batteries in 2001. It is not to be expected that any other battery system will offer portable electrical energy at a price being competitive to the carbon – zinc system. It will continue to be produced in large volumes probably with an increasing share of zinc chloride batteries. It is, however, to be expected, that the total percentage market share of carbon – zinc will decrease in favor of the alkaline manganese dioxide – zinc system.

6.1.1.2. Air – Zinc System

6.1.1.2.1. General

The air – zinc system with a weak acid electrolyte, like ammonium chloride, is a system of

the past. It belongs in principle to the group of carbon – zinc systems. H. COHEN [48] was probably the first to develop this system, which still is available on the market, although by now technically surpassed by other air – zinc systems. The IEC allocated system letter A to this system and addresses the positive electrode as oxygen electrode, which, however, has to be corrected to air electrode (cf. Section 6.1.3.4.1).

An interesting variant was developed in the 1960s. In this variant the ammonium chloride electrolyte was replaced by manganese(II) chloride in mixtures with magnesium chloride. This electrolyte was used in combination with a flat plate-construction for the air cathode (B. SILLER [49]) to improve the system's storage behavior, energy density and load capability. Although technically advanced it never attained market significance.

The alkaline version suggested by C. FÉRY [50] is much more promising in this respect. FÉRY obviously built the first successfully operated alkaline air – zinc cell (see Section 6.1.3.4).

6.1.1.2.2. Electrochemistry

The electrochemical active materials are

- Zinc, which represents the negative electrode,
- atmospheric oxygen in combination with a suitable porous carbon electrode, which represents the positive electrode, and
- the electrolyte, because it also participates in the reaction like in all carbon – zinc systems

The electrochemical reactions may be described by

Negative electrode

$$2\,Zn \longrightarrow 2\,Zn^{2+} + 4\,e^- \tag{6.11}$$

Positive electrode:

$$O_2 + 4\,e^- + 4NH_4^+ \longrightarrow 2\,H_2O + 4\,NH_3 \tag{6.12}$$

Electrolyte:

$$2\,Zn^{2+} + 4\,NH_3 + 4\,Cl^- \longrightarrow 2\,[Zn(NH_3)_2]Cl_2 \tag{6.13}$$

Overall reaction:

$$2\,Zn + O_2 + 4\,NH_4Cl \longrightarrow 2\,H_2O + 2\,[Zn(NH_3)_2]Cl_2 \tag{6.14}$$

Like all gas electrodes, also this air cathode needs to fulfil one important requirement: it must create a three-phase boundary, which is the reaction zone, otherwise it would not be operable. At the three-phase boundary the following phases are in contact with each other:

1) The oxygen of the air,
2) The electrolyte, and
3) The porous carbon electrode with sufficient catalytic activity for the electrochemical oxygen reduction according to Equation (6.1)

For a three-phase boundary to be established, the porous carbon structure must be partially hydrophilic – to allow for pores being filled with electrolyte – and partially hydrophobic to stay open for gas transport.

Like the ammonium chloride manganese dioxide – zinc system, also this air – zinc system produces zinc diammine chloride (Eq. 6.13), which precipitates in the electrolyte-filled pores of the air cathode. This process finally leads to a total blockage of the porous carbon structure, which means the battery's end of discharge. In other words: the porous volume of the carbon electrode, that is filled with electrolyte, determines the amount of electrical energy, that can be withdrawn from this system. This is the reason why this system needs rather thick porous air cathodes.

On the other hand a thick air cathode gives rise to a relatively high diffusion polarization (problems of mass transport), especially at higher currents. Thus the thickness of the air cathode must constitute a balance between the average power output in terms of, e.g., mW and the electrical energy in terms of Wh that may be obtained from the system. A typical thickness of an air cathode is of the order of several centimeters.

6.1.1.2.3. System-Immanent Properties

Again, the immanent properties of this system are directly correlated to its electrochemistry. This also includes the open circuit voltage. According to calculation the standard cell voltage is 1.73 V [45]. Since, however, the oxygen electrode is not a reversible one, the observed open circuit voltage is below this value, i.e., 1.45 V.

According to IEC, the nominal voltage is chosen to be 1.4 V.

The system's specific energy and energy density depends very much on the discharge conditions, including the environment (see below). At a current density of about 0.2 mA/cm^3 and ambient temperature typical values are of the order of

Specific Energy: 140 mWh/g

Energy density: 150 mWh/cm^3

Another system-immanent property is due to the fact that the system is open to the atmosphere, which is of course a requirement to permit oxygen to enter the system. However, simultaneously an exchange of water vapor proceeds between the system and its environment. Since the equilibrium humidity of ammonium chloride corresponds to about 80 % relative humidity, while the environmental humidity is normally below this value, the system tends to dry out after opening the air access. Due to water loss it may exhibit a rather low initial voltage on load that, however, will recover during operation, because water is produced according to Equation (6.12), thus compensating for the water loss during storage. In order to avoid an initial low voltage under load, the air access should be closed during storage or prolonged idle hours. From the above it follows that under extreme high humidity conditions, i.e., a relative humidity of the atmosphere > 80 %, the system would absorb water, which also would deteriorate the system's performance by time.

Another system-immanent property is the fact that the electrolyte of this air – zinc system does not absorb CO_2 from the atmosphere, in contrast to the alkaline air – zinc system. This is a property that makes the system suitable for long periods of operation, provided its humidity household is under control.

(Reaction 6.10 Section 6.1.1.1.3 also applies to this air – zinc system).

6.1.1.2.4. Batteries and Their Applications

In the air – zinc system the variety in battery sizes is limited in comparison to the batteries of the carbon – zinc system.

Cylindrical Batteries. The AR40 battery is presently the only cylindrical air – zinc battery listed in IEC Standard Publication 60086-2. It has a diameter of 67 mm and an overall height of 172 mm. Its internal construction is given in Figure 18.

Figure 18. Cross-section of an air – zinc battery IEC type AR40 (Ø = 67 mm; h = 172 mm)

The electrical energy is taken from the battery's screw terminals a and b. Terminal a is the negative pole being connected to the zinc can c, which is also part of the battery construction.

Screw terminal b is connected to carbon rod d, which is in contact with the active material e of the air cathode. The active material consist of a mixture of active carbon, graphite and electrolyte and forms a porous body that permits internal air diffusion. Around the porous body a separator paper f is wrapped. Within this porous body the oxygen of the air, the electrolyte and the active carbon are in contact with each other, forming the reaction zone, i.e., the three-phase boundary. The air enters the system via the air access openings g and h. The bottom of the cathode mix is separated from the can by a paper cup i. The gap between separator f and zinc can c is filled up with gelled electrolyte k. A card board washer j and a bitumen seal on top closes the battery. A card board cup l protects the zinc can c from outside.

The AR40 is offered also as multicell battery, having the IEC designation 5AR40. It comprises five AR40 cells connected in series to give a 7 V/85 Ah battery. The cells are arranged in a circle of 184 mm diameter at a height of 190 mm. When discharged, e.g., through a 500 Ω resis-

tor it delivers at ambient temperature on average 11.5 mA at 5.7 V for 365 d, i.e., 574 Wh.

Prismatic Batteries. The IEC standard lists two 8.4 V prismatic multicell batteries, carrying the IEC designation 6AS4 and 6AS6. They comprise six AS4 or six AS6 prismatic single cell batteries, connected in series. The characteristics of these multicell batteries are given in Table 2 for ambient temperature.

The design of the prismatic single cell batteries AS4 and AS6 is identical to the AR40 single cell battery shown in Figure 18.

The application of the air – zinc batteries with ammonium chloride electrolyte is in the area of low power output (e.g., 50 to 100 mW) for a long time (e.g., 5 to 12 month). Typical applications are industrial applications (e.g., barricade flashlight) and fence control. Another interesting application area is still the operation of emergency phones in areas where no power line is available.

Advantageous for this system is its portability and low price compared to other batteries and systems.

6.1.1.2.5. Prospects

In the mid-term future the air – zinc system should continue to be competitive in the low power/long term application field and in locations where no alternative power supply is available. In the long term it will probably disappear from the market.

6.1.2. Batteries with "Neutral Electrolyte"

Systems working with a true neutral electrolyte do not exist, because this kind of "electrolyte" would not have sufficient ionic conductivity [at 20 °C the ionic conductivity of pure water is ca. $5 \times 10^{-8}\,\Omega^{-1}\,\mathrm{cm}^{-1}$]. The term "neutral electrolyte" denotes natural water compositions like ocean water and fresh water of lakes and rivers. The term "activation" as used in the following refers to the method by which water is brought into the space between the battery's positive and negative electrode(s), which initiates the electrochemical reaction.

Magnesium Systems.

General. Several magnesium systems are known. Attention is drawn to the literature, e.g., to [51].

Magnesium systems are normally listed under "reserve batteries" (cf. Section 6.3). This is due to their specific properties like their excellent storage behavior (in a dry environment) before activation and their immediate readiness for use after activation (see also Section 6.1.3.4).

Electrochemistry. The more prominent magnesium system is the silver chloride – magnesium system. Because of the silver, it is also the most expensive magnesium system. Many attempts have been made in the past to replace the expensive AgCl with less expensive cathode materials such as Cu_2I_2, CuCl, CuSCN, $PbCl_2$, and others.

The technical performances of these systems are inferior to that of the silver chloride system.

The electrochemical reaction of the magnesium electrode (anode) is described by Equation (6.15)

$$\mathrm{Mg} \longrightarrow \mathrm{Mg}^{2+} + 2\,\mathrm{e}^- \tag{6.15}$$

For the silver chloride electrode Equation (6.16) applies

$$2\,\mathrm{AgCl} + 2\,\mathrm{e}^- \longrightarrow 2\,\mathrm{Ag} + 2\,\mathrm{Cl}^- \tag{6.16}$$

The overall reaction follows from Equations (6.15) and (6.16)

$$\mathrm{Mg} + 2\,\mathrm{AgCl} \longrightarrow \mathrm{MgCl_2} + 2\,\mathrm{Ag} \tag{6.17}$$

The electrochemical reaction of the magnesium – cuprous iodide system may serve as a second example. The chemical reaction at its negative electrode is described by Equation (6.15). For its positive electrode Equation (6.18) applies:

$$\mathrm{Cu_2I_2} + 2\,\mathrm{e}^- \longrightarrow 2\,\mathrm{Cu} + 2\,\mathrm{I}^- \tag{6.18}$$

The overall reaction of the magnesium – cuprous iodide system is

$$\mathrm{Mg} + \mathrm{Cu_2I_2} \longrightarrow \mathrm{MgI_2} + 2\,\mathrm{Cu} \tag{6.19}$$

The electrochemical reactions of the other magnesium systems proceed in an analogue manner. A unique feature of all magnesium systems is that they produce water soluble conductive salt,

Table 2. Air – zinc batteries (8.4 V), constant resistance discharge

Type, IEC designation	Length/width/height, mm	Discharge resistance, Ω	Capacity, Ah	Endpoint voltage, V
6AS4	168/113/114	300	53	5.1
6AS6	192/128/162	150	130	5.1

in the above examples magnesium chloride or magnesium iodine).

Because of the negative potential of the $Mg/Mg(OH)_2$-couple (approx. -1.7 V vs. SHE) a parasitic side reaction of magnesium with water is inevitable, i.e., the decomposition of water while generating hydrogen gas, which has the beneficial effect of stirring the "electrolyte" between the electrodes.

$$Mg + 2\,H_2O \longrightarrow Mg(OH)_2 + H_2 \tag{6.20}$$

Heat, as also generated by Equation (6.20), favors the battery performance in addition.

System-Immanent Properties. Values of some of the reported electrochemical system properties are listed in Table 3 [51].

According to Table 3 the energy density (mWh/cm^3) and the specific energy (mWh/g) of the magnesium – silver chloride system is approx. three times, respectively, two times as high as that of other magnesium systems. The magnesium – silver chloride system also has the highest discharge voltage, The magnesium lead chloride system has the lowest. The other magnesium systems are similar to the $Mg - Cu_2I_2$ system.

The operating temperatures of the above systems cover a range of $-60\,°C$ to $+65\,°C$. If stored in a dry atmosphere at ambient temperature the magnesium systems may be kept for an indefinite time without noticeable deterioration.

Batteries and Their Applications. Magnesium batteries are normally not available on the commercial market. They are designed for special applications.

Magnesium batteries exist in three different designs [51], i.e., immersion-type batteries, forced flow-type batteries, and dunk-type batteries.

1) *Immersion-type* batteries are activated by immersion into water after opening their water access wholes. Life vests, e.g., are equipped with this type of battery that uses the magnesium – cuprous iodide system to operate a 1.5 V × 0.2 A light bulb for 8 h in the case of emergency.
2) *Forced flow-type batteries:* The torpedo battery belongs to this type of battery. While the torpedo shoots through the sea water, water is driven through the electrode system of the battery, which is in this case a magnesium – silver chloride system. In combination with a water recirculation pump especially flat discharge curves of 1.1 V/cell at high current densities are obtained until the end of discharge.
3) *Dunk-type batteries:* Batteries of this type are activated by pouring water/electrolyte into the system. An absorbent separator is placed between its electrodes, which transports the water/electrolyte to the electrodes initiating thus their electrochemical reaction, while delivering electrical power. Batteries have been designed from 1.5 V up to 130 V at current outputs of up to 10 A [51]. Batteries of this type are used in radiosondes but also to power emergency transmitters. A battery of this kind is a 10.6 V × 10 Ah silver chloride – magnesium reserve battery for aircrafts.

Prospects. No change in market demand or application is expected: Magnesium batteries will continue to be specialists in the area of reserve batteries especially for rescue systems.

6.1.3. Batteries with Alkaline Electrolyte

Alkaline electrolytes offer more possibilities to realize battery systems than acid or neutral electrolytes. This is due to the fact that more metals and metal compounds are stable in alkaline electrolytes than in acid and weak acid electrolytes. The latter only permit zinc, carbon, and manganese dioxide to be used as electrochemical active substances or as electronic conductor (noble metals, titanium, etc., are stable but too expensive for primary batteries).

Table 3. Properties of different magnesium systems

Property	System		
	Mg – AgCl	Mg – Cu_2I_2	Mg – $PbCl_2$
Energy density, mWh/cm^3	180 – 300	50 – 120	50 – 120
Specific energy, mWh/g	100 – 150	50 – 80	50 – 80
Voltage under load∗, V	1.42 – 1.52	1.33 – 1.49	0.90 – 1.06

∗ at 5 mA/cm^2.

For alkaline electrolytes the situation is different. Quite a few metals and metal compounds are stable and have become electrochemical active materials and components of alkaline primary battery systems. They have enabled the development of several commercial battery systems. Metals and metal compounds of this kind are: Nickel, stainless steel, iron, cobalt, manganese, carbon, silver, copper, zinc, brass, mercury, and cadmium, including their oxides and hydroxides.

Another advantage is the high conductivity of alkaline electrolytes (e.g., 30 % KOH: $6 \times 10^{-1}\,\Omega^{-1}\,\mathrm{cm}^{-1}$) and the rather high rates at which electrochemical reactions occur without any impeding precipitates as in the case of carbon – zinc systems (cf. Section 6.1.1.1). This in turn means that diffusion polarization does not play a major role in alkaline battery systems with the exception of very high discharge rates.

Typical for all alkaline batteries is that after prolonged storage or use their negative terminal tends to present signs of leakage, which is of eminent importance, e.g., in the case of button batteries as used in high value devices like wrist watches. Electrolyte leakage is not always a phenomenon that is solely determined by the quality of seal. It is also influenced by a phenomenon that has to do with under-potential deposition [81] of the electrolyte's cations in alkaline solutions (cf. Section 6.1.3.2.4)

6.1.3.1. Manganese Dioxide – Zinc System

6.1.3.1.1. General

The alkaline manganese dioxide – zinc system has become the most important primary battery system. Its market share is constantly growing. The worldwide market for manganese dioxide-zinc batteries, including carbon – zinc, was reported in 1993 to be above 12×10^9 batteries [52] and will further have grown since then.

6.1.3.1.2. Electrochemistry

The electrochemical active materials are zinc (granulated powder) for the negative and electrodeposited γ-MnO_2 (EMD) for the positive electrode. KOH at a concentration of 40 % ($\pm$ 10 %) serves as electrolyte.

The electrochemical reaction of the negative electrode is given by Equation (6.21), which is the overall reaction of Equations (6.21a) and (6.21b).

$$\mathrm{Zn} + 2\,\mathrm{OH}^- \longrightarrow \mathrm{ZnO} + \mathrm{H_2O} + 2\,\mathrm{e}^- \tag{6.21}$$

$$\mathrm{Zn} + 2\mathrm{OH}^- \longrightarrow \mathrm{Zn(OH)_2} + 2\,\mathrm{e}^- \tag{6.21a}$$

$$\mathrm{ZN(OH)_2} \longrightarrow \mathrm{ZnO} + \mathrm{H_2O} \tag{6.21b}$$

The electrochemical reaction of the positive electrode is described by Equation (6.22) which is generally assumed to be a homogenous reaction for MnO_x in the range $2 > x > 1.5$ [53]:

$$2\,\mathrm{MnO_2} + 2\,\mathrm{e}^- + 2\,\mathrm{H_2O} \longrightarrow 2\,\mathrm{MnOOH} + 2\,\mathrm{OH}^- \tag{6.22}$$

The overall reaction is a combination of Equations (6.21) and (6.22)

$$\mathrm{Zn} + 2\,\mathrm{MnO_2} + \mathrm{H_2O} \longrightarrow 2\,\mathrm{MnOOH} + \mathrm{ZnO} \tag{6.23}$$

more likely to happen is the following reaction

$$\mathrm{Zn} + 2\,\mathrm{MnO_2} + 2\,\mathrm{H_2O} \longrightarrow 2\,\mathrm{MnOOH} + \mathrm{Zn(OH)_2} \tag{6.23a}$$

since Reaction (6.21b) is a rather slow process. Under high rate conditions the availability of water molecules in the cathode compartment may become crucial, as may become the availability of hydroxyl ions in the anode compartment, depending on the relative diffusion resistance

and the rate at which they are required. Reaction (6.23) or (6.23a) proceeds in the voltage range $1.55\ V > U > 1.0\ V$. A voltage plateau just above 1 V [54] is determined by Equation (6.24)

$$2\,MnOOH + H_2O + Zn \longleftrightarrow 2\,Mn(OH)_2 + ZnO \qquad (6.24)$$

The standard potential of Reaction (6.24), calculated from Gibbs free energies is 1.06 V [55]. When the reduction is continued at a discharge voltage $U < 1.06$ V Reaction (6.25) applies:

$$MnOOH + H_2O + e^- \longrightarrow Mn(OH)_2 + OH^- \qquad (6.25)$$

This is a heterogeneous reaction, being accompanied by an increase in cathode volume [56].

6.1.3.1.3. System-Immanent Properties

System-immanent properties of electrochemical systems have always two aspects. One is of thermodynamic the other one of kinetic origin. During discharge both influences superimpose each other.

The thermodynamic properties of the alkaline manganese dioxide – zinc system are similar in pattern to what was discussed in Section 6.1.1.1.3) in respect to the correlation between the state of discharge of manganese dioxide, the type of reduction reaction (homogeneous or heterogeneous) and its open circuit potential (cf. Fig. 11).

Calculated values of the open circuit voltage on basis of thermodynamic data for the manganese dioxide – zinc system deviate from experimentally observed values [45]. The observed open circuit voltage is 1.55 V and thus within the reported calculated value of carbon – zinc batteries. The open circuit voltage depends, however, also on the MnO_2 content. According to IEC Publication 86-1 the maximum open circuit voltage of the alkaline manganese dioxide – zinc system may attain up to 1.65 V [26].

Much work has been devoted to the kinetics of the manganese dioxide electrode [57], [58]. Special attention is drawn to the analysis of H. Laig-Hörstebrock [59], stating that during galvanostatic discharge the potential of the manganese dioxide electrode is basically controlled by two time-dependent processes, which are experimentally determinable. The experiments were carried out on a manganese dioxide disk-shaped sample, made of a mass mix being identical to what is used in primary batteries, including porosity and electrolyte. The thickness of the MnO_2 disk was chosen to be $d = 2$ mm. Potential measurements were carried out simultaneously on both sides of the disk. The galvanostatic load, however, was applied only to one of its two sides.

The difference in potential $\Delta\varphi$ of both sides was determined. During the initial phase the potential difference changed according to Equation (6.26)

$$\Delta\varphi = S_I t^{1/4} \qquad (6.26)$$

i.e., it is proportional to the speed at which the current penetrates the porous system (S_I = const). In parallel to the current penetration the reduction reaction by proton diffusion into the MnO_2 lattice comes into play, a model being well established [60–62]. The overall reduction reaction is described by

$$MnO_2 + x\,H_2O + x\,e^- \longrightarrow MnOOH_x + x\,OH^- \qquad (6.27)$$

with x being the fraction of diffusing protons. The process comes to an end as soon as the current has penetrated the full electrode thickness (for $d = 2$ mm after approx. 1 min). At this point the electrode potential is only controlled by proton diffusion, which is described by Equation (6.28)

$$\varphi = S_{II} t^{1/2} \qquad (6.28)$$

Constants S_I and S_{II} of Equations (6.26) and (6.27) are derived on basis of theoretical considerations [59] being related to the MnO_2 disk and the proton diffusion [63]. The results are that the potential of the MnO_2 electrode is only controlled by the resistance of the electrolyte diaphragm of the MnO_2 disk and the proton diffusion and not by resistances such as the electronic resistance of the MnO_2 particles and the charge transfer.

It is reasonable to assume that the same factors are rate determining in the reduction of MnO_2 cathodes in carbon – zinc batteries. Their experimental determination, however, is difficult because of the marked influence of the diffusion polarization in carbon – zinc cells (cf. Section 6.1.1.1).

Another system-immanent property has to do with the zinc and the fact that its potential is ca. – 0.42 V versus the hydrogen electrode in the same electrolyte, thus that Reaction (6.29) occurs, if not inhibited.

$$Zn + H_2O \longrightarrow ZnO + H_2 \quad (6.29)$$

This problem is identical in nature to that discussed in Section 6.1.1.1.3. It is, however, more pronounced in the case of the alkaline system, because this system uses zinc powder, having a relatively large surface area and thus producing a relatively high amount of hydrogen gas if not properly inhibited. For safety reasons all alkaline manganese dioxide – zinc batteries have a rupture vent included, that opens when the internal gas pressure exceeds a predetermined value, thus avoiding a rupture of the battery.

In the past the amalgamation of zinc powder, i.e., treatment with mercury to form an alloy, has proven best in avoiding any critical rates of hydrogen evolution. However, the use of mercury was banned for environmental reasons. Costly research programs resulted finally in the development of highly purified zinc powder, which in combination with additives like indium and organic inhibitors, permitted to produce an anode material providing gassing rates being equivalent to that of amalgamated zinc powder.

When assuming an average discharge voltage of 1.3 V the following values for the specific energy and the energy density are obtained:

Specific energy: 272 mWh/g
Energy density: 1132 mWh/cm^3

These values are purely theoretical and exceed significantly the experimental values. When discharging a modern premium grade LR20 battery at a low current density [i.e., 0.3 mA/cm^3, endpoint voltage 0.9 V (endpoint voltage 0.9 V was chosen because practically all IEC discharge regimes for the manganese dioxide zinc systems are based on this voltage)], the following experimental discharge values may be verified:

Specific energy: 170 mWh/g
Energy density: 400 mWh/cm^3

In comparison to the carbon – zinc system (cf. Section 6.1.1.1.3) these experimental values are higher by 40 % in respect to the specific energy and by 100 % as regards the energy density, although these values are obtained at twice the discharge rate (0.3 mA/cm^3 compared to 0.15 mA/cm^3). These values demonstrate already in part the superior performance of the alkaline manganese dioxide system over the carbon – zinc system.

The experimental values are typically well below the theoretical values (cf. Section 6.1.1.1.3), i.e., the theoretical values consider only the active materials according to Equation (6.23), while assuming 100 % Faraday efficiency. The theoretical values do neither consider weight and volume of the inactive materials like the steel can, the separator, the current collector; nor additives like graphite and carbon black; nor the grommet or contact arrangements.

The difference between theoretical and practical values of the energy density is especially high. This also results from the porosity of the cathode and the low density of the zinc powder (approx. 3 g/cm^3). Since the endpoint voltage was chosen to be 0.9 V, the experimental values will also include a contribution from Equation (6.25), i.e., they are not based just on Equation (6.23) or (6.23a), respectively.

For increasing discharge currents the voltage under load continues to drop, depending on the current and the degree of discharge. However, in comparison to the carbon – zinc system the diffusion polarization is much smaller (see Fig. 19). In comparison to Figure 12 the performance of the LR14 battery is significantly better. Under continuous load conditions the battery provides still 89 % of the discontinuous discharge result, whereas the zinc – carbon systems provide only 27 %, respectively 58 %. The alkaline manganese dioxide – zinc system is therefore suitable for both: continuous and discontinuous discharge.

Figure 19. IEC type LR14 continuous (24 h/d) and discontinuous (4 h/d) discharge through a 3.9 Ω resistor

6.1.3.1.4. Batteries and Their Applications

Alkaline manganese dioxide – zinc batteries exist in three shapes: prismatic, cylindrical, and button. The more important batteries are listed in the IEC Standard [33]. To differentiate carbon – zinc batteries from alkaline manganese – dioxide zinc batteries by nomenclature, the alkaline system was given letter L by the IEC system (see Table 4).

Prismatic Batteries. All standardized prismatic batteries are multicell batteries constructed from 3 to 6 cylindrical cells, and connected in series. Relevant nominal voltages vary from 4.5 V (three cells) to 9 V (six cells).

The 6LR61 is a rather well known battery. It is the alkaline version of the 6F22 battery (cf. Section 6.1.1.1.4). The 6LR61 battery offers 500 mAh, i.e., twice the capacity of the 6F22. Like the 6F22 it has a nominal voltage of 9 V, the same external dimensions (26.5 mm × 17.5 mm × 48.5 mm) and identical terminal arrangements. Its internal construction, however, is different from the 6F22 battery (cf. Fig. 15). The 6LR61 is constructed of six alkaline manganese – zinc cylindrical cells, size R61 connected internally in series. Figure 20 displays a battery of this kind.

Figure 20. IEC type 6LR61 9 V battery
The top plate of this prismatic battery carries the terminals (spring loaded snap contacts). The battery contains six cylindrical 1.5 V round cells (LR61). Top and bottom plate carry inside connectors that connect the cells in series to give a 9 V battery. The six round cells are encapsulated in a metal jacket.

The applications for this 9 V battery includes those of the 6F22, i.e.,

- Remote control,
- Smoke detectors,
- Electrical multi-meters,
- Toys, and
- Transistor radios

In addition it permits higher rate applications, e.g., in personal tape recorder. Another well known prismatic battery is the 4.5 V 3LR12 battery which is the alkaline version of the 3R12 battery, however, with more than twice the capacity, i.e., 5900 mAh. Construction and typical applications are identical to the 3R12 battery (cf. Section 6.1.1.1.4), i.e., it is used in portable lighting and transistor radios. The 3LR12 battery also permits higher rate applications.

Cylindrical Batteries. A cross-section of a cylindrical battery is given in Figure 21. The construction is identical to the so-called rechargeable alkaline manganese – zinc battery (see Section 6.1.3.1.4).

Figure 21. Schematic cross-section of a cylindrical alkaline manganese dioxide – zinc battery

The construction shown in Figure 21 is known as *inside-out* construction, which refers to the battery's polarity. In comparison to the carbon – zinc battery (cf. Fig. 13) the MnO_2 cathode is no longer inside but outside the internal battery construction. It is in direct contact with the nickel-plated steel can, while the anode (zinc powder) is arranged in the center

of the construction. In order to be interchangeable with "carbon – zinc" batteries the terminal arrangements had be changed, such that the negative electrode offers a flat external contact area, while the positive terminal is represented by the steel can which imitates the physical envelope of a carbon rod at its end. Furthermore the cylindrical part of the steel can requires an electrical insulation.

Table 4 lists five standard cylindrical batteries of system L, and zinc – chloride batteries of the same size, including their dimensions and typical applications. For comparison typical capacity values are listed for both systems. These values again demonstrate the superior capacity of the alkaline battery system.

This is especially true for high continuous discharge currents as illustrated in Figure 22. Under the conditions chosen, the R14S provides only 8.6 % and the R14P just 27 % of the capacity provided by the LR14 battery. For low rate and/or discontinuous applications, however, carbon – zinc batteries are still a good choice (cf. Section 6.1.1.1.4). Because of their present high market demand R6-sized batteries are produced worldwide at very high production volumes.

Figure 22. 3.9 Ω continuous discharge of R14S, R14P, and LR14 batteries

Besides single cell cylindrical batteries, also multicell cylindrical batteries are under production, which are constructed from in series connected button cells.

Button batteries are usually referred to as *button cells* although they comply with the criteria for single cell batteries. Single cell button batteries are characterized by their physical shape that resembles a button. Primary button batteries, using an alkaline electrolyte have a maximum diameter of $d = 11.6$ mm. The ratio between their diameter d and their height h is typically $1.5 < d/h < 6$. A schematic drawing of a LR-button battery is given in Figure 23.

Figure 23. Schematic drawing of a (single cell) button battery

Presently five popular sizes for the manganese dioxide-zinc system are available on the market (see Table 5).

Multicell button batteries are constructed from several single cells as a pile, being connected in series, while having a common cylindrical envelope. They are available with different nominal voltages like 6 V, 12 V, 15 V and 22.5 V. For this type of batteries diameter ≤ height is valid. They therefore may be called *multicell cylindrical batteries*.

The *application* of multicell button batteries is manifold. Their predominant application is in the area of photo- and remote control equipment. Also single cell button batteries find widespread application. Specific application areas are electronic equipment like small hand held calculators with LCD display and low cost wrist watches.

6.1.3.1.5. Rechargeable Alkaline Manganese Dioxide – Zinc System

Rechargeable batteries are subject of Chapter 7. Since, however, some of the background of the rechargeable alkaline manganese dioxide – zinc system is already given in Section 6.1.3.1.2, the system's rechargeability will be discussed here.

The rechargeable alkaline manganese dioxide – zinc system was pioneered by K. V. Kordesch and co-workers ([64] and references cited therein, [56], [65]). One of the more attractive properties of this system is its low cost in comparison to other rechargeable systems.

True rechargeable systems are reversible systems in both respects: electrode structure and

LR44	11.6	5.4	1.5	120

electrochemistry. In the manganese dioxide-zinc system of the reactions occurring at the manganese dioxide electrode only Reaction (6.22) complies with this requirement (or Reaction 6.23, respectively, which also includes the zinc electrode). This reaction takes place in the voltage range 1.55 V $> U >$ 1.0 V. Below 1.06 V Reaction (6.25) proceeds, which is accompanied by an increase in volume. This reaction is irreversible and is therefore to be avoided in order to maintain the system's cyclability.

The reaction occurring at the zinc electrode, (Eq. 6.21), is electrochemically reversible. Not reversible, however, is its structure on recharge (shape change, see also Section 4.1.1.2). Furthermore, after the first charge the deposited zinc is much finer than the originally granulated zinc powder, which may lead (in the discharged state) to zinc particles being electronically isolated thus lowering the zinc electrode's capacity. This can be counteracted by the addition of graphite. Hydrogen gassing, being typical for all zinc systems, is inhibited by the addition of organic inhibitors. Nevertheless, the rechargeability of the manganese dioxide – zinc system is limited.

Furthermore, when charging the system it must be ensured that the charge voltage is limited to 1.65 – 1.68 V. Charging to higher voltages produces soluble manganese species and oxygen which oxidizes the zinc and/or increases the internal pressure, both processes resulting in a loss of cycle capacity. In no case a constant-current charger should be employed. This could lead to an uncontrolled built-up of internal gas pressure, such that the safety vent of the battery may open, permitting the electrolyte to escape.

The dimensioning of the zinc electrode determines the capacity and thus roughly the endpoint voltage of the battery. A better choice would be a voltage control by, e.g., electronic means to avoid the two-electron step (Eqs. 6.22 and 6.25), which occurs below 1.06 V. If not, the endpoint voltage of discharge will approach 0.8 V. Under this condition it takes about 20 discharge cycles until the capacity drops to about 50 % of the initial capacity, which is 70 % of that of the primary battery. The number of useful cycles and cycle capacity increases, when the cells are not deep discharged to below 0.9 V but only partially

discharged, while avoiding the irreversible two-electron discharge step.

An endpoint voltage of 0.9 V leads to much better results (see Fig. 24). In Figure 24 the cycle capacity and cumulative capacity for a R6(AA)-sized battery are plotted versus the number of cycles. An interesting result is that the cycle capacity decays linearly with the logarithm of cycle number.

Figure 24. Cycle capacity and cumulative capacity versus the logarithm of cycle numbers of rechargeable alkaline manganese – zinc batteries

The construction of the rechargeable alkaline manganese dioxide – zinc battery is practical identical to that of the primary version (cf. Fig. 21). Essential differences exist, however, in the composition of the positive and the negative electrodes, i.e., to impede hydrogen gassing, to improve oxygen evolution during charge and to enhance cycle life, while limiting the discharge preferably to the one-electron step of Equation (6.22).

The rechargeable alkaline manganese dioxide – zinc battery is offered in the standard sizes R03(AAA), R6(AA), R14 (C) and R20 (D), all of which are cylindrical batteries. The highest specific load capability is offered by the small sized batteries because of their relatively thin cathodes.

The application of the single cell battery is practically identical to its primary version, which is also true for its storage behavior (in a charged state). If connected in parallel to so-called bundle-cells the discharge current may be increased to the needs of the application.

6.1.3.1.6. Prospects

The prospects of the primary alkaline manganese dioxide – zinc system are very promising as already pointed out (cf. Section 6.1.3.1.1). The future success of the rechargeable version of the alkaline manganese dioxide – zinc battery will not only depend on the system's characteristics but also on the consumer. Which system he will give preference will determine whether or not a substantial market will develop. This market will probably be identical to the market of present primary standard cylindrical batteries. New markets for the rechargeable version may open up, especially in the area of applications that only need low-rate shallow cycles in the voltage range 1.5 to 1.0 V per cell. In principle also high-rate applications are not out of range. The rechargeable alkaline manganese dioxide – zinc battery is, however, not expected to replace systems used in present automotive starting applications [66] like, e.g., the lead – acid system.

6.1.3.2. Silver Oxide – Zinc System

6.1.3.2.1. General

The silver oxide – zinc system exists in two variants. Variant 1 uses monovalent silver oxide Ag_2O while variant 2 is based on divalent silver oxide AgO. Variant 1 permits the construction of silver oxide batteries offering a relatively high energy density at a high load capability, including a flat discharge characteristic.

Batteries made by use of the divalent silver oxide system offer ca. 30 % more capacity in comparison to the monovalent silver oxide – zinc system. Silver is a precious metal and as such expensive. Much work has therefore been dedicated in the past to commercially employ the divalent silver oxide system, unfortunately so far with limited success, apart from a few years where they were in production.

6.1.3.2.2. Electrochemistry

Divalent Silver Oxide – Zinc System. The first step of electrochemical reduction of the divalent silver oxide is described by Equation (6.30)

$$2\,AgO + H_2O + 2\,e^- \longrightarrow Ag_2O + 2\,OH^- \qquad (6.30)$$

In combination with the electrochemical zinc oxidation according to

$$Zn + 2\,OH^- \longrightarrow ZnO + H_2O + 2\,e^- \quad (6.31)$$

the overall reaction of the first reduction step is derived

$$2\,AgO + Zn \longrightarrow Ag_2O + ZnO \quad (6.32)$$

Using the values of the Gibbs free energies the standard voltage of Equation (6.32) is calculated to be $U = 1.837$ V.

Since the electronic conductivity of AgO is poor, the AgO powder needs to be mixed with some conductive material like graphite. Under this condition the system's d.c. resistance is still relatively high and permits only a low rate discharge according to Equation (6.32), resulting in a discharge plateau at approx. 1.8 V.

Monovalent Silver Oxide – Zinc System. As soon as all of the divalent silver oxide is reduced to monovalent silver oxide according to Equation (6.32) the continuation of the reduction process follows Equation (6.33). Since the electronic conductivity of Ag_2O is even worse than that of AgO, the availability of conductive material in the Ag_2O powder is crucial, at least initially. As soon as metallic silver Ag is produced according to Equation (6.33) the system's internal resistance drops by about a factor of 30 to rather low values and the system becomes finally a high-rate system permitting discharge loads corresponding to current densities of up to 100 mA/cm^2 and even above [67].

On discharge the monovalent silver oxide – zinc system reacts in a heterogeneous reaction, which is reflected by a flat discharge characteristic. It is based on cathode reaction (6.33) and anode reaction (6.34)

Cathode reaction

$$Ag_2O + H_2O + 2\,e^- \longrightarrow 2\,Ag + 2OH^- \quad (6.33)$$

Anode reaction

$$Zn + 2\,OH^- \longrightarrow Zn(OH)_2 + 2\,e^- \quad (6.34)$$

Reaction (6.34) is followed by a decomposition of zinc hydroxide according to Reaction (6.35)

$$Zn(OH)_2 \longrightarrow ZnO + H_2O \quad (6.35)$$

The overall reaction is

$$Ag_2O + Zn \longrightarrow 2\,Ag + ZnO \quad (6.36)$$

The standard voltage of Reaction (6.36) is $U = 1.593$ V. The discharge voltage plateau at a medium discharge rate stabilizes at ca. 1.55 V.

The overall reaction that includes both discharge steps is given by

$$2\,AgO + 2\,Zn \longrightarrow 2\,Ag + 2\,ZnO \quad (6.37)$$

6.1.3.2.3. System-Immanent Properties

The theoretical values of the two discharge plateaus are:

First voltage plateau ($U = 1.83$ V)
Specific Energy: 259 mWh/g
Energy density: 1899 mWh/cm^3
Second voltage plateau ($U = 1.59$ V)
Specific Energy: 225 mWh/g
Energy density: 1651 mWh/cm^3

The total of both discharge plateaus is obtained by their addition:

Specific Energy: 484 mWh/g
Energy density: 3550 mWh/cm^3.

The applicability of the silver oxide system would undoubtedly increase, if it could be modified such that it offered the capacity of the divalent silver oxide at the discharge voltage and load capability of the monovalent silver oxide – zinc system.

Much work has been devoted in the past to this task [68–72]. The scientific background of this work was primarily built on the findings of Wales, Burbank, and Dirkse [73].

The basic idea of the development work was to (electro-)chemically reduce the surface of the AgO powder particles according to Equation (6.30) such that the AgO particles are covered by a layer of Ag_2O. In the second step these Ag_2O/AgO particles are contacted with metallic silver, either by adding a small amount of metallic silver powder, or by chemical and/or electrochemical reduction. Under this condition the potential of the Ag_2O/Ag electrode is realized, although most of the silver oxide is still in its divalent state. In combination with a zinc anode a voltage of 1.59 V is established while the

system offers the desired high load capability of the monovalent and the extended capacity of the divalent silver oxide zinc system.

At a first glance the above ideas appear simple and easy to realize. This is indeed true for batteries being put into service shortly after the reduction treatment or if stored only for a short period of time. For long term storage (a couple of months) problems are most likely to arise for the following reasons:

It is difficult to really produce a tight Ag_2O layer around all of the individual AgO particles, such that the AgO phase does not get into contact with the alkaline electrolyte.
If it gets into contact with the electrolyte the divalent silver oxide will decompose and/or oxidize the metallic silver.

At ambient temperature the decomposition reaction of divalent silver oxide occurs relatively slowly

$$2\,AgO \longrightarrow Ag_2O + \tfrac{1}{2}\,O_2 \tag{6.38}$$

However, in a hermetically sealed battery this will lead to a noticeable pressure built-up during storage, especially at elevated temperatures. Reaction (6.38) needs therefore to be inhibited. This can be achieved by the addition of, e.g., gold oxide [74], lead and/or cadmium compounds, which means either a relatively expensive treatment or the addition of environmentally harmful compounds.

The other obstacle of the "electrolyte-contacted AgO" is, that it oxidizes the surface of the metallic silver

$$AgO + Ag \longrightarrow Ag_2O \tag{6.39}$$

The voltage will only be stable at 1.59 V if the Ag surface is large enough in relation to the AgO surface being in contact with the electrolyte. If the Ag surface is oxidized before the AgO is consumed the potential of the system will rise again to that of the AgO/Ag_2O system, which – in combination with the zinc electrode – means a voltage of 1.83 V (cf. Eq. 6.32). Simultaneously the internal resistance rises again to its initial high value. However, on discharge the voltage plateau of the monovalent silver oxide – zinc system is reached again rather quickly.

Another important component is the *separator*, which determines the storage life of the silver oxide battery. In contrast to other cathode materials like MnO_2 and HgO, silver oxide is quite soluble in alkaline solutions (approx. 50 mg/L). The ions present in the alkaline solution are reported in the literature as $Ag_3O(OH)_2^-$, $Ag(OH)_2^-$ or AgO^- [75], [76]. Cellophane was the first separator that made it possible to manufacture silver oxide – zinc cells with a reasonable shelf life [77]. Since 1970 highly improved separator systems have become available [78], [79]. They are based on stable materials like grafted polyethylene (PE) or polypropylene (PP) in combination with laminates of cellophane. The separator system has been studied in detail [80] with the result that the diffusion of dissolved silver oxide species through the separator, an important factor for self-discharge, can be excluded. More important is the influence of self-discharge resulting from the oxidation of organic cell components and the cellophane. Decisive is the separator's tendency to allow for the formation of metallic silver bridges, their resistance being in the range of 0.5 to 12 kΩ. The formation of silver bridges is governed by statistical influences, i.e., after a long term storage some cells out of many may still exhibit nearly their full capacity while others are partially or even fully discharged.

The system employs a zinc (powder) electrode as anode, which is responsible for another system-immanent property, i.e., hydrogen evolution. The problems involved are identical to what has already been discussed (see, e.g., Section 6.1.3.1.3, Eq. 6.29).

Typical for the monovalent silver oxide – zinc system is its rather flat discharge curve and its rather low internal resistance. At a current density of 0.5 mA/cm^2 its discharge voltage is in the range $1.5\,V > U > 1.6\,V$ during 90 % of discharge time at less than $30\,\Omega \times cm^2$ (d.c. resistance).

6.1.3.2.4. Batteries and Their Application

Because of its high material costs, the commercial application of this system is limited to small sized batteries like button batteries, having an energy content of less than 0.5 Wh. For military application, however, battery units of up to 20 kWh have been realized (cf. Section 6.3.1).

The IEC system letter for the monovalent silver oxide zinc system is S. In combination with letter R, i.e., SR, a round battery is addressed, which includes both, cylindrical and button batteries. The divalent silver oxide system was designated with letter T as long a it was an IEC standardized system.

Batteries made from the Monovalent Silver Oxide – Zinc System. The single cell button battery is the most common construction for the alkaline silver oxide – zinc system in commercial application. The construction is practically identical to that shown in Figure 23.

Because of the problem of electrolyte leakage caused by under-potential deposition (see Section 6.3.1) there are two versions of silver oxide – zinc button batteries in use. The version that employs KOH is especially used for high rate applications, e.g., to power light emitting diodes (LEDs). The battery's lifetime in high-rate applications is relatively short, such that leakage problems do not show up during its active service life.

For long-term applications (i.e., low rate discharge) preference is given to the NaOH electrolyte. Its resistance is higher than that of the KOH electrolyte but the tendency to cause leakage at the negative electrode is – for above reasons – significantly reduced [82].

More than 25 different sizes of silver oxide – zinc button batteries are available on the market. Present batteries cover following ranges of dimensions and capacities:

Diameter: $5.8\,\text{mm} \leq \phi \leq 11.6\,\text{mm}$
Height: $1.25\,\text{mm} \leq h \leq 5.4\,\text{mm}$
Capacity: $5\,\text{mAh} \leq \text{c} \leq 170\,\text{mAh}$

Their specific energy and their energy density are far below the theoretical values and depend very much on battery size: The smaller the battery, the smaller its corresponding energy value due to the increasing percentage of inactive weight and volume of battery piece parts. Typical values are in the range of:

Specific energy: $52\,\text{mWh/g} < E*(\text{w}) < 113\,\text{mWh/g}$

Energy density: $235\,\text{mWh/cm}^3 < \text{E}*(\text{v}) < 462\,\text{mWh/cm3}$

If the electrochemical active materials would determine weight and volume of the battery, its specific values would increase to

Specific energy: 350 mWh/g (extrapolated value)

Energy density: 700 mWh/cm^3 (extrapolated value)

Since their main application is in the area of electronic wrist watches they are primarily addressed as *watch batteries*; but they are also in use in some photo applications.

Batteries made from the Divalent Silver Oxide – Zinc System. Button batteries constructed from the divalent silver oxide – zinc system to enter the market in 1974 – 1975. For larger sized button batteries they offered a capacity being 35 % above the capacity of the monovalent silver oxide zinc system. This was of considerable interest in those days when LED wrist watches were largely in use, because these wrist watches have a high current demand, especially in combination with additional functions. In the following decades, however, the technology changed and electronic wrist watches became smaller and smaller, while their current demand dropped. Consequently the batteries became smaller too. Smaller sized divalent silver oxide button batteries, however, offered less than an 35 % capacity advantage over the version with monovalent silver (see above).

This change in technology led finally to the disappearance of the divalent silver oxide system from the market, which in part was also due to the processing costs and difficulties to have its voltage stabilized.

6.1.3.2.5. Prospects

The divalent silver oxide system may come back if the market should demand again larger-sized high drain silver oxide – zinc button batteries. The monovalent silver oxide – zinc system is expected to remain in the commercial market as a button battery. It will continue to be the ideal energy source to power multifunction high quality wrist watches, photo devices, and appliances that need a constant voltage source, while offering a good rate capability.

6.1.3.3. Mercuric Oxide – Zinc System

6.1.3.3.1. General

The mercuric oxide – zinc system was pioneered by SAMUEL RUBEN [83] and developed during World War II. The system is known for its high energy density, constant voltage, good load capability, good temperature and excellent storage behavior. An important requirement for an excellent storage behavior is, among others, the use of high purity mercuric oxide, which renders the system relatively expensive.

In spite of its favorable performance characteristics the use of mercuric oxide – zinc battery has increasingly declined within the last decade because of the environmental problems involved. Whenever possible it is replaced meanwhile by other systems like lithium-based batteries, alkaline manganese dioxide – zinc, silver oxide – zinc, and air – zinc systems. A detailed description of the mercuric oxide – zinc system including battery sizes and their application etc. is given in [84].

6.1.3.3.2. Electrochemistry

Since mercuric oxide is a poor electronic conductor it has to be mixed with graphite to allow the cathode reaction (Eq. 6.40) in an alkaline electrolyte at reasonable rates

$$HgO + H_2O + 2e^- \longrightarrow Hg + 2OH^- \tag{6.40}$$

in combination with the anode reaction (Eq. 6.41)

$$Zn + 2OH^- \longrightarrow ZnO + H_2O + 2\,e^- \tag{6.41}$$

the overall reaction (Eq. 6.42) is derived

$$HgO + Zn \longrightarrow Hg + ZnO \tag{6.42}$$

6.1.3.3.3. System-Immanent Properties

Based on Gibbs free energies a standard voltage of $U^o = 1.35$ V is calculated from Equation (6.42), which is in good agreement with experimental observations. Theoretical values on specific energy and energy density are calculated from Equation (6.42) as well. They are solely based on active materials:

Specific energy: 256 mWh/g
Energy density: 2526 mWh/cm^3

Corresponding values of commercial products are far below. Larger sized products (R20 size and above) may reach values (extrapolated) up to:

Specific energy: 160 mWh/g
Energy density: 800 mWh/cm^3

Smaller sized button batteries at a capacity of 50 to 450 mAh cover a range of

Specific energy: 80 – 130 mWh/g
Energy density: 380 – 550 mWh/cm^3

Mercuric oxide is not readily soluble in the alkaline electrolyte, i.e., any self-discharge due to dissolved species does not occur. In comparison to silver oxide, mercuric oxide has a rather low oxidation potential, such that it does not attack the separator system.

A less favorable system-immanent property is the formation of microdroplets of mercury, generated during discharge according to Reaction (6.40), which may agglomerate. If so, larger agglomerations may finally cover up areas of active material and impede its reaction. Fortunately graphite powder being added (3 % to 10 %) to improve the cathode's electronic conductivity assists in the prevention of mass agglomeration of mercury droplets as do other additives like manganese dioxide. This addition increases the cell voltage to approx. 1.4 V.

A careful selection is also required for the separator system. Its porosity must be such that it by no means permits the penetration of microdroplets of mercury, which otherwise could establish electron conducting bridges with subsequent self-discharge. Another requirement is the mechanical stability of the separator in alkaline electrolyte (e.g., 30 % KOH) over prolonged periods of time at elevated temperatures (e.g., 40 to 60 °C). The identical requirement exists for the battery's plastic seal.

Typical for the mercuric oxide – zinc system is its nearly constant voltage discharge. At a current density of 0.5 mA/cm^2 its discharge voltage is in the range $1.35\,V > U > 1.30\,V$ during approx. 90 % of discharge.

Another system-immanent property are unfortunately the ecological problems involved. These problems have made the mercuric oxide – zinc system practically disappear from the commercial market. As long as the battery is hermetically sealed no problem exists. There would also be no problem if approx. 100 % of sold batteries would be returned after use for recycling. Since this cannot be enforced, batteries may be disposed off uncontrolled and open up one day by, e.g., corrosion or mechanical force, such that its contents may get into contact with the environment and form soluble compounds. The worst case would be the formation of soluble organic compounds, since they exhibit the highest toxicity.

6.1.3.3.4. Batteries and Application

System letter of the IEC for the mercuric oxide – zinc system was letter M. In combination with letter R, i.e., MR, a round battery was addressed. Meanwhile the mercuric oxide – zinc system is no longer included in the IEC Standard Public. 86 [26], [33].

The prevailing application of this miniature battery has been in the area of hearing aids, electronic wrist watches, photo and all kinds of electrical instruments. In this application area the prevailing construction is/was the button battery. The constructional details are identical to those shown in Figure 23.

Besides button batteries also cylindrical batteries exist(ed) on the market at nominal voltages between 2.7 and 7 V and capacities of 150 up to 1000 mAh.

6.1.3.3.5. Prospects

There is still a large number of electronic devices which only work properly on mercuric oxide – zinc batteries. As long as these devices are in use, the demand for mercuric oxide batteries will continue. But in the long term these devices will be replaced, the production of mercuric oxide batteries will probably fade away.

It is safe to assume that – because of the system's ecological problems – it will not be employed again in any new commercial application.

6.1.3.4. Alkaline Air – Zinc System

6.1.3.4.1. General

The IEC has allocated system letter P to the alkaline air – zinc system. The IEC, however, addresses this system as the "oxygen alkali metal hydroxide zinc" system, which actually should be changed to read the "air alkali metal hydroxide zinc" system, since there are distinct differences between the two systems. In contrast to the air electrode the oxygen electrode of the alkaline oxygen – zinc battery does practically not have any gas diffusion problems and therefore would permit a different construction. The reason for the diffusion problems of the air electrode (especially at higher discharge rates) is the high nitrogen content of the air (ca. 80 vol %). In consequence of this the alkaline oxygen – zinc system has a much higher rate capability than the alkaline air – zinc system and in addition a slightly higher open circuit voltage due to the higher partial oxygen pressure. It furthermore needs no fan for gas circulation as needed for larger air – zinc battery systems. Another principal advantage of the oxygen – zinc system over the air – zinc system is the fact that it is a closed system, i.e., there is no exchange of gaseous species between the system and its environment.

In comparison to the air – zinc system, however, the oxygen – zinc system has one big disadvantage: It needs a special container to store the oxygen, which increases the systems volume, weight, and costs. This is probably the reason why no commercial application for the oxygen – zinc system has emerged so far.

Figure 25. Schematic drawing of the cross-section of an air – zinc button battery including a close-up drawing of its air cathode arrangement

The alkaline air – zinc system is known since 1925 at the latest (cf. Chap. 2). The system's key component is its air cathode, which may be considered as a spin-off of fuel cell gas-electrode technology. A fuel cell gas-electrode needs – to be operable – also a three-phase boundary [85] being composed of the gas phase (air), the catalytic phase (electronic conductor) and the ion conducting phase (electrolyte). In this context the development of hydrophobic compounds like polytetrafluoroethylene was crucial. This is the reason why the system's commercialization did not start before the early 1970s [86].

Figure 25 is a schematic cross-section of an air zinc button battery with a close-up of its air cathode. The thickness of this multilayer air cathode is approximately 0.5 mm. In comparison to the air cathode of the weakly acidic ammonium chloride – zinc system (see Section 6.1.1.2), which has a thickness of ca. 3 cm, this air cathode is extremely thin. This is one of the reasons for its high load capability, i.e., low diffusion polarization. Depending on battery size up to four air access holes are placed into the bottom of the cathode can.

6.1.3.4.2. Electrochemistry

The electrochemical oxygen reduction can be described by Reaction (6.43)

$$\frac{1}{2}\,O_2 + H_2O + 2e^- \longrightarrow 2\,OH^- \qquad (6.43)$$

This reaction proceeds at the three-phase boundary of the porous air cathode, as already described above.

The reaction of the zinc powder electrode is identical to what has already been described in Section 6.1.3.1.3.

$$Zn + 2\,OH^- \longrightarrow ZnO + H_2O + 2\,e^- \qquad (6.44)$$

Equation (6.44) is simplified. The potential-determining reaction is given by [87]

$$Zn + 4\,OH^- \longrightarrow Zn(OH)_4^{2-} + 2\,e^- \qquad (6.44a)$$

it is succeeded by the decomposition reaction

$$Zn(OH)_4^{2-} \longrightarrow ZnO + H_2O + 2\,OH^- \qquad (6.44b)$$

The overall reaction is derived from Equations (6.43) and (6.44)

$$\frac{1}{2}\,O_2 + Zn \longrightarrow ZnO \qquad (6.45)$$

6.1.3.4.3. System-Immanent Properties

The alkaline air – zinc system is remarkable in various aspects:

The standard potential of Equation (6.45), calculated under equilibrium conditions from Gibbs free energies, is $U^0 = 1.647$ V which may be realized under ultrapure conditions (i.e., absence even of traces of reducing substances [88]). Under practical conditions, however, the reversible potential is not established. The OCV of an practical air – zinc cell tends to be 200 mV below the standard value, i.e., approx. 1.44 V. This is reportedly influenced by a hydrogen peroxide mechanism acting in parallel [89].

Furthermore, the partial oxygen pressure in the case of air is approx. only 1/5 of the standard value as used for the calculation of the oxygen standard potential, which, however, accounts only for a few millivolts less (a decrease in oxygen pressure by a factor 10 decreases the equilibrium potential only by 15 mV and vice versa).

As a single cell battery the alkaline air – zinc battery has the highest energy density of all electrochemical systems. A button battery offers up to 1200 mWh/cm^3 at 365 mWh/g. These specific values drop for larger multicell battery units to 250 mWh/cm^3 and 170 mWh/g, if auxiliary equipment like fan, heat exchanger, humidity control, etc., are necessary for system operation [90].

At ambient temperature its load capability is equal if not higher than that of the mercuric oxide – zinc system, i.e., 30 mA/cm^2 and above, depending on the potential of the uncovered cathode, when exposed to air.

The system is environmentally benign and therefore a very good replacement for the mercuric oxide – zinc system, especially in the hearing aid application.

A comparison of the design of the air – zinc battery and other zinc systems, explaining the high energy density of the air – zinc system, is given in Figure 26.

Both button batteries use the same number of components. However, in contrast to the mercuric oxide – zinc battery the air – zinc battery must not store its oxidant (atmospheric oxygen). Therefore the air-zinc battery can store more zinc than the mercuric oxide – zinc battery, which explains its higher energy content. However, the anode compartment of the air – zinc battery must in addition provide some extra space, because of the volume increase by 65 % due to Reaction (6.45). Otherwise the air – zinc battery would swell and leak on discharge. The same arguments are valid in comparison to other metal oxide batteries like the silver oxide – zinc and the manganese dioxide – zinc system.

Figure 26. Cross-section of an air – zinc button battery in comparison to a mercuric oxide – zinc button battery

Besides these advantages the air – zinc system has one significant disadvantage in comparison to other systems. This is due to the fact that the system is open to air. Under this condition two deteriorating processes are acting in parallel. The carbonation of the alkaline electrolyte and exchange of water with the environment.

$$2\,\mathrm{KOH}\ (\text{electrolyte of battery} + \mathrm{CO_2}\ (\text{from outside}) \longrightarrow \mathrm{K_2CO_3} + \mathrm{H_2O} \qquad (6.46)$$

Equation (6.46) describes the carbonation of the KOH electrolyte by carbon dioxide that diffuses through the air access opening into the battery's interior. Although the air contains only 0.03 % carbon dioxide it will by and by use up the alkaline electrolyte, and thus increase the electrolyte's resistance. The final result is given by Reaction (6.46).

In parallel to Reaction (6.46) water is exchanged in the form of vapor either leaving the battery and diffusing away into the environment or coming from the environment and being absorbed as described by Reaction (6.47). The direction of diffusion is determined by the difference in relative humidity ΔRH between the inside of the battery RH_i and the environment RH_e.

$$\mathrm{H_2O}\ (\text{battery}) \longleftrightarrow \mathrm{H_2O}\ (\text{environment}) \qquad (6.47)$$

Typical values for the relative humidity inside the battery are in the range $50\ \% < RH_\mathrm{i} < 60\ \%$, depending on the concentration of the KOH-electrolyte. The environmental humidity RH_e varies in the range $10\ \% < RH_\mathrm{e} < 95\ \%$, the low value is represented, e.g., by a desert climate or an electrically heated room in wintertime without humidifier. The high value being represented by a wet environment, e.g., a tropical climate, a rainy day or an in-house sauna.

To illustrate the consequences of the environmental humidity and related properties, three different cases are discussed below:

1) Low environmental humidity: $\Delta RH > 0$; $RH_\mathrm{i} > RH_\mathrm{e}$.
   The air – zinc battery will dry out, a process additionally favored by Reaction (6.46). As a consequence the battery's internal resistance will increase, which finally leads to a bad battery performance and a short battery life. This effect is sometimes referred to as self-discharge, which is not correct since this effect has nothing to do with electrochemistry. The above effect may not be noticed if the battery is discharged quickly enough before it has lost too much water and/or if the condition $\Delta RH > 0$ lasts only for a short time and/or if its value is very small.
2) High environmental humidity: $\Delta RH < 0$; $RH_\mathrm{i} > RH_\mathrm{e}$
   The air – zinc battery will pick up additional water from outside. Under this condition the battery will swell and may finally leak. This situation becomes worse when the battery is additionally discharged, because when zinc is oxidized to zinc oxide according to Reaction (6.45) its partial molar volume increases by ca. 65 %.
   The above effect may not be noticed if the battery is discharged quickly enough before substantial amounts of water have been absorbed and/or if the condition $\Delta RH < 0$ lasts only for a short time and/or if it is very small.

3) Equilibrium humidity: $\Delta RH = 0; RH_i = RH_e$
This is the ideal case since Equation (6.47) is in equilibrium and would thus permit an unlimited storage life. This, however, is only true in a CO_2 free atmosphere, which unfortunately does not exist. Because of Equation (6.46), the relative humidity RH_i inside the cell would constantly rise to higher values thus initiating the process as already described in case 1), although at a much lower rate.

6.1.3.4.4. Air Access Opening: Its Seal and Diffusion Resistance

To ensure a good storage behavior of the air – zinc system its air access opening(s) must be absolutely sealed during storage to avoid deteriorating transport processes according to Equations (6.46) and (6.47).

When closing the air access opening(s), the system is deactivated, i.e., no current can be drawn anymore. Small batteries, like button cells, have typically one to four air access holes (depending on size, load capability and storage behavior), which have to be sealed during storage. This is usually done by an adhesive foil, preferably a metal foil. Plastic tape, e.g., is not suitable for very long storage periods, since it would permit the diffusion of oxygen, water vapor, and carbon dioxide, although at a highly reduced rate. Of significant importance is furthermore the adhesive that glues the foil to the battery surface. The adhesive must last at least the time of storage. It must further be ensured that the hydrogen evolution at the anode is minimized to an acceptable degree (cf. Section 6.1.3.1.3, Eq. 6.29). Otherwise the foil would be lifted, resulting in a bad storage behavior. Before use the foil must of course be removed from the battery (*activation*). In this respect the air – zinc battery may also be considered as a reserve battery (see Section 6.3).

Larger battery systems, using, e.g., a fan for air supply and circulation have other constructional means to suppress Reactions (6.46) and (6.47). They employ, e.g., flaps for the air in- and outlet and a CO_2 scrubber to eliminate the carbon dioxide from the air.

An interesting characteristic of the air – zinc battery is its limiting current i_L given by Equation (6.48)

$$i_L = G D_{O_2} \frac{4F}{RT} \Delta p^o_{O_2} \tag{6.48}$$

The limiting current i_L is defined for the case that the partial pressure of oxygen at the three-phase boundary (i.e., reaction zone) of the oxygen electrode is zero, i.e.

$$\Delta p_{O_2} = p^o_{O_2} - p^b_{O_2} = p^o_{O_2}; p^b_{O_2} = 0$$

$p^o_{O_2}$: partial oxygen pressure outside the battery
$p^b_{O_2}$: partial oxygen pressure at three-phase bondary
D_{O_2}: oxygen diffusion coefficient
G: geometric electrode factor

The limiting current i_L is experimentally determined by means of a voltage – current diagram. When constantly increasing the current the voltage finally drops more than proportionally. The limiting current is the current that causes in the end an abrupt drop in electrode potential. A typical diagram for a PR44 button battery (see Table 6) is given in Figure 27. The PR44 battery has two air access holes symmetrically arranged within the bottom area of the cathode can, each one having an diameter of ca. 0.5 mm and being separated from each other by ca. 5 mm.

Figure 27 presents two current – voltage diagrams with a sharp voltage drop at their end, which is related to a limiting current. With two air access holes the limiting current is ca. 22 mA. With one air access hole the limiting current is about half of it, i.e., 12 mA. The i_L value for the unprotected open air cathode is 100 mA, i.e., 150 mA/cm^2.

Figure 27. Current – voltage diagram and limiting current i_L of a PR44 air – zinc battery

Table 6. Air – zinc button batteries for hearing aids (presently standardized single cell button batteries, IEC code P)

IEC type	Diameter, mm	Height, mm	Nominal voltage, V	Typical capacity, mAh
PR	5.8	2.15	1.4	33
PR70	5.8	5.8	1.4	60
PR41	7.9	3.6	1.4	130
PR48	7.9	5.4	1.4	230
PR44	11.6	5.4	1.4	540

For the air – zinc system under given conditions the limiting current is proportional to the mass transport according to Equations (6.46) and (6.47), i.e., a high limiting current means a high rate of water loss (depending on $\Delta RH > 0$) and vice versa. The same is true for the rate of carbon dioxide pick-up, i.e. the higher the limiting current, the higher the absorption rate of carbon dioxide (depending on the partial pressure of CO_2).

Normal current loads $i < i_L$, should not exceed 1/2 of the limiting current i_L in order to realize an acceptable discharge voltage of the air – zinc battery. Therefore, if a given battery is able to supply 100 mA constant current while the application demands only 10 mA, the diffusion resistance should be increased to provide only 10 mA at an acceptable discharge voltage. This avoids an unnecessary high rate of water loss and CO_2 pick up during battery operation, resulting thus in a prolonged service life of the battery.

This optimization principle allows to realize, with otherwise identical battery parts, either a high-rate battery, having a relatively short service life after activation, or a low-rate battery having a relatively long service life, just by adapting the diffusion resistance to the current needs of the application.

6.1.3.4.5. Batteries and Their Application

Because of their attractive high energy density and high specific energy content, there have been many attempts to construct special air – zinc batteries, even as mechanically rechargeable batteries in the area of vehicle propulsion [91], [92] with an energy content of up to 110 kWh at approx. 50 kW power output. So far, however, all these activities have failed to enter the commercial market for various reasons, with the exception of primary button batteries. Button batteries are mainly applied in the area of hearing aids and to a smaller extent in electronic pagers.

Besides its electrical/electrochemical attractiveness the air – zinc system is, in comparison to the mercuric oxide – zinc system, also an environmentally benign system. Since the discharge voltage of the air – zinc system is close to that of the mercuric oxide – zinc system, and this at an improved energy density and load capability, it became soon its ideal replacement. The capacity of identical sized button batteries of the mercuric oxide – zinc system is by a factor 2.5 less than that of the air – zinc system which also has favored the replacement of the mercuric oxide – zinc system. Best results with air – zinc batteries are obtained if the hearing aid is used 12 to 14 h per day. Dissatisfaction will arise if the air – zinc hearing aid battery would be used only occasionally (e.g., once a week), because it probably will dry out before its stored electric energy is used up.

Presently five different button battery sizes are available on the market, designed to power different types of hearing aids (see Table 6).

The first column lists the international designation according to the IEC (manufacturer's designations differ in general from IEC designations). As can be seen from Table 6 the smallest type of air – zinc button batteries has not been standardized yet.

6.1.3.4.6. Prospects

In order to be successful in a given application, a new system must offer a technical, environmental and/or economical advantage over the existing system.

In the area of hearing aid batteries the air – zinc system has been very successful. It is therefore expected that this system will continue to stay in the market.

In general the alkaline air – zinc system should have good prospects in all those applica-

tions that discharge the battery to its end-point before it starts to deteriorate noticeably due to mass transfer according to Equations (6.46) and (6.47). The air – zinc system should also be very useful as a reserve system to be activated via electrolyte and/or air in application areas where a low weight and small volume are decisive.

Since the air cathode is not used up during discharge it should generally be possible to use it in a rechargeable system. Recharging could occur either mechanically (i.e., replacing the discharged zinc by fresh zinc and fresh electrolyte) or electrically by reducing the zinc(II) to metallic zinc. Both methods have been studied extensively in the past [91] and later by AER Energy Resources, Inc., Smyrna, Georgia, USA, however, so far without commercial success. Among other problems it is obviously difficult to develop an air cathode with a three-phase boundary, that is locally stable within the electrode's porous structure while remaining active over a sufficient length of time on repetitive use.

If present problems should be overcome it would be easy to predict a number of new commercial applications for the alkaline air – zinc system.

6.2. Batteries with Nonaqueous Electrolyte

Electrochemical battery systems employing a nonaqueous electrolyte are governed by lithium metal as anode material, in combination with a suitable cathode material. These batteries are characterized by some outstanding properties like a high energy density, high specific energy, low self-discharge, and a wide temperature range, within which they can be operated.

Several cathode materials (solid and soluble) and several nonaqueous electrolytes (organic and inorganic), were developed in the past. Certain combinations of both allow to compose different lithium battery systems with different characteristics regarding voltage, load capability, capacity, storage behavior, etc.

Table 7. Three crucial properties of lithium in comparison to zinc

Property	Lithium	Zinc
Standard potential∗	− 3.045 V∗	− 0.76 V∗
Density	0.534 g/cm^3	7.13 g/cm^3
Specific capacity	3.86 Ah/g	0.82 Ah/g

∗ Standard potentials of metal ion electrodes at 25 °C in aqueous solution according to Latimer [93]

In this section some typical properties of these lithium battery systems will be presented, including their construction. Presentation will be limited to those that have attained market significance, apart from some exceptions.

The reason to devote research and development activities to batteries employing lithium as anode material is based on its extraordinary properties. Three of them are listed in Table 7 in comparison to zinc.

Lithium's affinity to react with water has, however, initially retarded technical battery development work (until the 1960s). Lithium reacts with water according to Equation (6.49) rather vigorously under practical conditions, producing lithium hydroxide, hydrogen, and heat.

$$2\,Li + 2\,H_2O \longrightarrow 2\,Li^+ + 2\,OH^- + H_2 \qquad (6.49)$$

Reaction (6.49) is valid for all aqueous electrolytes.

The first task was therefore to develop suitable non-aqueous electrolyte(s).

Nonaqueous Electrolytes. A nonaqueous electrolyte is suitable for lithium batteries if it offers the following properties:

1) Stability in contact with lithium
2) Sufficiently high ionic conductivity
3) Compatibility with the cathode material
4) Safety on handling
5) Environmental friendliness
6) Low cost

Nonaqueous electrolytes may be grouped into organic electrolytes, inorganic electrolytes, electrolytes with soluble cathode, and solid electrolytes.

Liquid electrolytes consist in general of a mixture of solvents with the addition of lithium-based conductive salt(s). Today it is generally accepted that none of the known solvents is thermodynamically stable in contact with lithium [94]. The commercial success of primary lithium

batteries is actually based on a passivating protective layer between the electrolyte and the surface of the lithium electrode [95]. The composition and thickness of this protective layer depends on the composition of the electrolyte and its purity. This protective interphase is called *solid electrolyte interphase* (SEI). It is, among others, responsible for the excellent storage behavior of lithium battery systems.

The SEI represents a layer of relatively low conductivity and causes initially a voltage drop upon application of a discharge load. On continuation of the load, however, the layer is reduced in thickness, which leads to a significant increase of its conductivity and consequently to a decrease of the initial voltage drop [96]. This phenomenon is called *voltage delay* (see Fig. 28). For more information on the SEI see [97].

Figure 28. Schematic drawing of the initial voltage – time transient (voltage delay) in response to discharge current $i = c$
OCV = open circuit voltage ($i = 0$); CCV = closed circuit voltage ($i = c$); TMV = transition minimum voltage; RT = recovery time of the CCV until it becomes constant.

The parameters *transition minimum voltage* (TMV) and *recovery time* (RT), depicted in Figure 28, depend very much on the type of lithium system, the discharge load, and preceding storage conditions. TMV and RT generally increase with increasing discharge load, decreasing discharge temperature, and long preceding storage periods at elevated temperatures. The voltage delay is less pronounced for systems with organic electrolyte and solid cathode than in systems with soluble cathode materials, like thionyl chloride ($SOCl_2$) and sulfur dioxide (SO_2). Values of RT may reach up to 10 s.

In comparison to aqueous electrolytes, liquid nonaqueous electrolytes offer larger temperature ranges of operation, down to below − 150 °C [98] and up to above 300 °C [99] and voltage windows up to several volts. Their drawbacks are lower conductivity in comparison to aqueous systems (factor 10 to 100 and above), higher costs, inflammability, and environmental problems. For more information on nonaqueous electrolytes, see, e.g., [100].

Certain nonaqueous electrolytes fit best only certain cathode materials, they will be dealt with in the relevant sections.

Processing Techniques. Besides suitable nonaqueous electrolytes, also new processing techniques had to be developed to handle lithium metal in battery production, i.e., to protect it from any reaction with the ambient atmosphere, especially from air humidity. To be acceptable for sensitive operations, humidity must be reduced to the ppm range. Thus, relevant *dry rooms* had to be developed. Dry rooms also solved problems during handling of the nonaqueous electrolyte, i.e., its addition to the electrode system before battery closure. Under normal humidity conditions (50 % to 60 % RH) the electrolyte would absorb to much humidity from the atmosphere during addition to the system and thus become unusable.

For special operations (research, small production volumes, storage, etc.) *glove boxes* are still in use, normally with an argon atmosphere inside. The glove box system permits to control not only the humidity but also the oxygen content of the inside atmosphere to very low levels if required.

6.2.1. Batteries with Organic Electrolyte

Systems using an organic electrolyte may be subdivided into systems having an operating voltage of approx. 3 V and systems with approx. 1.5 V. They all employ solid cathode materials, such as V_2O_5, Ag_2CrO_4, MoO_3, MnO_2 (3 V systems) and FeS_2, CuO, and Bi_2O_3 (1.5 V systems). The more important ones will be described below.

6.2.1.1. Manganese Dioxide – Lithium System

6.2.1.1.1. General

The manganese dioxide – lithium system was one of the first systems with solid cathode. It was pioneered by Sanyo Electric Co. The company started the development work in 1975 and has finally granted their manufacturing technology to more than 12 international operating battery manufacturers. Today the manganese dioxide – lithium system is the most widely spread commercial lithium primary battery system in the world. It is manufactured in various shapes and sizes such as cylindrical, button, and prismatic batteries.

The IEC has allocated system letter C to the manganese dioxide – lithium system. Example: CR2032 designates a round battery (R) of the MnO_2 – Li system (C), having a diameter of 20 mm and a height of 3.2 mm. Since $d > h$ applies, the round battery is a button battery by definition (for battery designation see also Chap. 8).

6.2.1.1.2. Electrochemistry

The simplified reaction for this system is described by:

Anode reaction

$$Li \longrightarrow Li^+ + e^- \tag{6.50}$$

Cathode reaction

$$MnO_2 + Li^+ + e^- \longrightarrow MnO_2^- \ (Li^+) \tag{6.51}$$

Overall reaction

$$MnO_2 + Li \longrightarrow MnO_2^- \ (Li^+) \tag{6.52}$$

where MnO_2^- (Li^+) symbolizes that the lithium ion is introduced into the MnO_2 crystal lattice [101], i.e., an intercalation compound is formed. The cathode material is a specially prepared and heat-treated form of MnO_2. The electrolyte consists generally of a solvent-mix of propylene carbonate (PC) and 1,2-dimethoxyethane (DME) with lithium perchlorate ($LiClO_4$) as conducting salt. At high discharge rates, the limited diffusion rate of Li^+ ions into the pore system of the MnO_2 cathode may result in a depletion of the conducting salt in the cathode pores, thus causing a premature end of discharge [102]. For this reason, cathodes for high rate discharge generally do not exceed 1 mm in thickness. They need a metal grid for mechanical support, which serves simultaneously as current collector.

6.2.1.1.3. System-Immanent Properties

Voltage characteristics:

Maximum off-load voltage: 3.7 V [26]
Theoretical off-load voltage: 3.5 V [103]
Nominal voltage: 3 V [26]

Under standard discharge conditions the voltage is 2.9 V [26], which is experimentally verifiable.

If based on a theoretical voltage of 3.5 V the following theoretical energy values may be calculated:

Energy density: 3100 mWh/cm^3
Specific energy: 1000 mWh/g

Practical values depend on battery size, internal construction, discharge load, and temperature.

Under low-rate conditions and at ambient temperature the following maximum values may be obtained from bobbin-type cylindrical batteries:

Energy density: 720 mWh/cm^3
Specific Energy: 260 mWh/g

6.2.1.1.4. Batteries and Their Applications

The applications of a manganese dioxide – lithium battery depend on its shape, size, and internal construction.

Button batteries are defined by diameter > height. Because of their flatness, lithium button batteries are addressed also as *coin cells*. Their ratio d/h is typically in the range: $6 < d/h < 12$ (see Fig. 29). For normal button batteries the ratio is typically $d/h < 6$.

Figure 29. Cross-section of a manganese dioxide – lithium button battery

So far 21 manganese dioxide – lithium button batteries have been standardized [26], [33]. Their dimensions cover the following range

$$10.0\,\text{mm} \leq d \leq 30.0\,\text{mm}$$
$$1.2\,\text{mm} < h \leq 5.0\,\text{mm}$$

Their capacities range from 25 to 500 mAh. A typical discharge curve of a button battery is given in Figure 30.

From the voltage difference $U_b - U_t$ and the relevant change in discharge current the internal resistance R_i is calculated. Typical – as for most batteries – is the increase of the internal resistance with increasing degree of discharge. The capacity loss of these batteries during storage is of the order of 1 % per year and below. It is influenced also by the quality of the seal, the storage conditions and the purity of the materials used.

Figure 30. Discharge curve (U_b) of a CR2032 battery discharged through a 5.6 kΩ resistance with a superimposed pulse of 390 Ω for 2 s every 2 h, designated (U_t). R_i is the internal resistance of the battery.

Applications. Low-rate applications are typical for this type of battery (watches, small calculators, memory back-up, and cameras).

Figure 31. Bobbin-type construction of a cylindrical MnO_2 – Li battery [100]

Cylindrical Batteries. Of approx. 20 cylindrical MnO_2 – Li batteries available on the commercial market, so far six batteries have been standardized. Some of them are bobbin-type constructions for low-rate applications. Others employ spirally wound electrodes to comply with high rate requirements.

The *bobbin-type construction* is similar in electrode arrangement to the alkaline manganese dioxide – zinc battery (see Fig 21). A cross-section of a MnO_2 – Li bobbin-type cylindrical battery is presented in Figure 31.

Table 8 lists four cylindrical batteries with bobbin-type construction for low-rate application. A typical low-rate application is memory back-up in various kinds of electronic devices including computers.

Cylindrical *batteries with spirally wound electrodes* are designed for high-rate applications. Some of the more important batteries are listed in Table 9. The main application for these batteries is in the field of multifunction automatic cameras and heat meters (CR11108). A cross-section of a spirally wound cylindrical battery is presented in Figure 32.

Table 8. Cylindrical MnO_2 – Li batteries with bobbin-type electrodes for low-rate application

IEC Battery designation	Diameter, mm	Height, mm	Voltage, V	Capacity, mAh
CR12600	12.0	60.0	3	1500
CR14250	14.5	25	3	850
(CR17335)	17.0	33.5	3	1800
CR17450	17.0	45.0	3	2500

( ) = not standardized yet.

Table 9. Cylindrical MnO_2 – Li batteries with spirally wound electrodes for high rate application

IEC Battery designation	Diameter, mm	Height, mm	Voltage, V	Capacity, mAh
CR11108	11.6	10.8	3	180
2CR11108	13	25.2	6	170
(CR15H270)	17.0	27.0	3	750
(CR17335)	17.0	33.5	3	1300
CR17345	17.0	34.5	3	1300
CR17450	17.0	45.0	3	2000

( ) = not standardized yet.

Figure 32. Cross-section of a high-rate lithium battery with spirally wound electrodes [125]

The high-rate capability of this battery is achieved by its large electrode area, its thin electrodes and its low-resistance separator. Figure 33 illustrates the discharge behavior of a cylindrical battery with spirally wound electrodes. If standardized it would carry the designation CR17335 (diameter 17.0 mm, height 33.5 mm), capacity 1300 mAh. Battery 17335 exists also as low-rate battery, with a nominal capacity of 1800 mAh (see Table 8). If standardized, the present IEC nomenclature system would designate both of them as CR17335 since the present designation system does not differentiate between a low-rate and a high-rate lithium battery. This ambiguity needs to be eliminated.

Figure 33. Discharge behavior of a high-rate battery CR17335 at different temperatures, discharge current 500 mA [125]

The construction according to Figure 32 offers short-period power outputs of up to 400 mW/cm^3(cf. Section 4.2.4). Constructions of this type are equipped with at least one safeguarding device (c.f. Section 5.2.2) to avoid battery rupture or explosion in case of an internal or external short circuit that would heat up the battery, thus causing an excessive internal pressure built up. The positive temperature coefficient (PTC) device reduces an external short circuit to an acceptable current level.

This kind of battery is relatively expensive because of its construction, safety features, ac-

tive materials, and production costs. It therefore will hardly be used, e.g., to power toys or torches. In this case batteries with aqueous electrolyte offer the better choice. Their specific energy cost is lower by a factor 6 to 8.

Prismatic Batteries. So far only two prismatic batteries of system C have been standardized by the IEC. They are not true prismatic batteries by construction, since both contain two cylindrical cells with spirally wound electrodes connected in series. Their nominal voltage is 6 V. Further details are given in Table 10.

Both batteries are designed to operate automatic cameras (film transport, flash light, shutter, light meter, etc). They could in principle be used also for medium- to low-rate applications, which, however, could be prohibitive by their price, because cheaper alternatives exist.

6.2.1.1.5. Prospects

The manganese dioxide – lithium system is currently the most successful primary lithium system on the commercial market. Presently only rough estimates exist on the worldwide production volume. The production volume of lithium button batteries was estimated in 1998 to be 10 % of that of alkaline MnO_2 batteries, i.e., 1.8×10^9 batteries, tendency increasing [120].

6.2.1.2. Carbon Poly-monofluoride–Lithium System

6.2.1.2.1. General

The carbon poly-monofluoride – lithium system $(CF)_n$ – Li was developed by Matsushita Battery Industrial Co. in the early 1970s. Since then batteries were developed in various shapes and sizes like button, cylindrical, prismatic, and pin-type batteries.

Their characteristics are similar to those of the MnO_2 – lithium system. The $(CF)_n$ – Li system is used primarily at low to medium discharge rates [104]. Advantageous is the large temperature range (− 40 °C to + 85 °C) within which it can be operated [105]. Carbon poly-monofluoride is an intercalation compound, formed by reaction between carbon powder and fluorine gas at elevated temperatures [106].

The IEC has allocated system letter B to the $(CF)_n$ – Li system [26]. Example: BR2325 designates a round battery (R) of the carbon poly-monofluoride – lithium system (B), having a diameter of 23.0 mm and a height of 2.5 mm. Since $d > h$ applies, this round battery is a button battery.

6.2.1.2.2. Electrochemistry

The discharge reaction is described by

Anode reaction

$$n\mathrm{Li} \longrightarrow n\mathrm{Li}^+ + n\mathrm{e}^- \tag{6.53}$$

Cathode reaction

$$(\mathrm{CF})_n + n\mathrm{e}^- \longrightarrow n\mathrm{C} + n\mathrm{F}^- \tag{6.54}$$

Overall reaction

$$n\mathrm{Li} + (\mathrm{CF})_n \longrightarrow n\mathrm{C} + n\mathrm{LiF} \tag{6.55}$$

Typical electrolytes are [104]: Lithium hexafluorarsenate ($LiAsF_6$) in dimethylsulfite (DMSI) Lithium tetrafluoroborate ($LiBF_4$) in a mixture of butyrolactone (BL) and tetrahydrofuran (THF) or of propylencarbonate (PC) and dimethoxyethane (DME).

6.2.1.2.3. System-Immanent Properties

According to IEC [26] the system's maximum off-load voltage is 3.7 V and its nominal voltage 3 V. Its theoretical specific energy is 2260 mWh/g [104]. The system's practical energy density and specific energy range up to

Energy density: 600 mWh/cm^3
Specific energy: 250 mWh/g

The system offers a low self-discharge of 0.5 % per year.

6.2.1.2.4. Batteries and Their Applications

Button Batteries. Of the 12 button battery sizes being produced, six have presently been standardized by the IEC. Their range is given by

$$12\,\mathrm{mm} \leq \text{diameter} \leq 30.0\,\mathrm{mm}$$

Table 10. 6 V high-rate prismatic batteries for automatic cameras

Designation accepted by IEC	Length, mm	Width, mm	Height, mm	Capacity, mAh
2CR5	34	17	45	1520
CR-P2	35	19.5	36	1300

$1.6\,\text{mm} \leq \text{height} \leq 3.2\,\text{mm}$
$48\,\text{mAh} \leq \text{capacity} \leq 190\,\text{mAh}$

The cross section of a $(CF)_n$ – Li system button battery is identical to that of Figure 29. The discharge behavior of battery type BR2032 (d = 20 mm, h = 3.2 mm; capacity 190 mAh) is given in Figure 34 A and compared to the discharge behavior of battery type CR2032 (210 mAh) under identical conditions (see Fig. 34 B). The comparison according to Figure 34 exhibits slight advantages for the MnO_2 – Li system over the $(CF)_n$ – Li system regarding both, voltage and capacity.

The commercial applications of the $(CF)_n$ – Li button batteries are identical to those of system MnO_2 – Li (watches, small calculators, memory back-up, etc.).

Cylindrical and Prismatic Batteries. The following cylindrical and prismatic batteries are standardized by the IEC:

1) Low-rate type BR17335:
   Nominal voltage 3 V; capacity 1.2 Ah; $d = 17.0$ mm; $h = 33.5$ mm
2) High-rate type BR17345:
   Nominal voltage 3 V; capacity 1.2 Ah; $d = 17.0$ mm; $h = 34.5$ mm

Their applications are identical to batteries CR17335 and BR17345 of the MnO_2 – Li system (e.g., memory back-up and automatic cameras).

An interesting comparison between a BR17335 battery and an R6P carbon – zinc battery (cf. Section 6.1.1.1.4) is given in Figure 35 for three different temperatures (20 °C, 0 °C and – 10 °C). The B-system battery uses spirally wound electrodes, the carbon – zinc battery is a bobbin-type construction. The discharge resistances are selected such that comparable discharge currents are drawn from the batteries. Although smaller by approx. 9 % in volume, the B-system battery offers at 20 °C approx. 3.5 times more energy than the carbon – zinc battery.

Figure 35. Comparison between a BR17335 battery and a R6P carbon – zinc battery

A specialty of the $(CF)_n$ – Li system is the so-called *pin-type battery* (BR425), used for fishing rods (illumination of the "fishing controller" during night time). Type BR425 is characterized by: Nominal voltage 3 V, capacity 25 mAh, diameter 4.2 mm, height 25.9 mm. Since $d < h$ applies, this battery is a cylindrical battery by definition, probably the smallest one in the world. A larger version of the BR425 is the BR435 (50 mAh).

Battery type BR-P2 is a 6 V high-rate prismatic battery for automatic cameras, see Table 11. It has the same application as the 6 V CR-P2 battery and is also constructed from two cylindrical high-rate batteries, connected in series. Larger prismatic batteries of the $(CF)_n$ – Li system with capacities of 25 Ah and above [104] are designed for applications in the noncommercial market.

6.2.1.2.5. Prospects

The carbon poly-monofluoride – lithium system is produced by one battery manufacturer [107]. Commercial markets being exclusive for this system are unknown with the exception of the pin-type battery. It appears that in regional and noncommercial markets as well as in special-purpose applications the $(CF)_n$ – Li system will

Figure 34. Constant resistance discharge (15 kΩ) of button batteries (diameter 20 mm, height 3.2 mm) at 60 °C, 20°C, and − 10 °C
A) BR2023 (190 mAh); B) CR2023 (210 mAh)

Table 11. BR and CR 6 V-high rate prismatic batteries for automatic cameras

Designation accepted by IEC	Length, mm	Width, mm	Height, mm	Capacity, mAh
BR-P2	33.9	19.5	36	1200
CR-P2	35	19.5	36	1300

continue to be an interesting alternative to other lithium systems.

6.2.1.3. Iron Disulfide – Lithium Systems

6.2.1.3.1. "1.5 V" Lithium Systems

The iron disulfide – lithium system (FeS_2 – Li) belongs to the group of "1.5 V" lithium systems like iron sulfide – lithium (FeS – Li), copper oxide – lithium (CuO – Li), bismuth plumbate – lithium ($Bi_2Pb_2O_5$ – Li, bismuth trioxide – lithium (Bi_2O_3 – Li) and others [104]. Much research and development work has been put into these systems in the 1970s. It was hoped that these systems could replace the expensive silver oxide – zinc or the environmentally harmful mercuric oxide – zinc button batteries to operate watches and/or hearing aids [108].

The above expectations could, however, not be realized. The main reason for this is the high internal resistance of these batteries, which is partly caused by the small diameter of the button battery: To be interchangeable with existing 1.5 V button batteries only standard diameters of 11.6 mm, 9.5 mm, 7.8 mm, or 5.8 mm are allowed. Under this condition existing 1.5 V button battery systems with alkaline electrolyte have a much lower resistance (factor 100 and above).

Another hope was that 1.5 V lithium systems could replace existing 1.5 V cylindrical batteries in low-rate applications. This was realized to a certain extent by the CuO – Li system [104]. Its excellent storage capability, high energy density, and wide temperature range has made it an interesting special-purpose battery, that, however, never will become a serious competitor for user-replaceable commercial 1.5 V cylindrical batteries.

More success on the commercial market is expected for the iron disulfide – lithium system, developed by the Eveready Battery Co., USA. The system is acknowledged by the IEC, and has received system letter F for identification. So far, however, only one battery size is available on the market. It is a R6-sized battery (diameter 14.5 mm, height 50.5 mm, capacity 2.6 Ah, nominal voltage 1.5 V) containing spirally wound electrodes.

6.2.1.3.2. Electrochemistry

The reaction (simplified) for the iron disulfide – lithium system is described by:

Anode reaction:

$$4\,Li \longrightarrow 4\,Li^+ + 4e^- \tag{6.56}$$

The cathode reaction proceeds in two steps

Step 1:

$$FeS_2 + 2\,Li^+ + 2e^- \longrightarrow FeS + Li_2S \tag{6.57a}$$

Step 2:

$$FeS + 2\,Li^+ + 2\,e^- \longrightarrow Fe + Li_2S \qquad (6.57b)$$

Overall reaction:

$$4\,Li + FeS_2 \longrightarrow Fe + 2\,Li_2S \qquad (6.58)$$

A mixture of propylene carbonate–dimethoxyethane with dissolved lithium perchlorate as conducting salt serves as electrolyte.

Figure 36. Low-rate discharge of a R6-sized FeS_2 – Li battery, (discharge resistance 5 kΩ) [125]

6.2.1.3.3. System-Immanent Properties

According to IEC the system's maximum off-load voltage is 1.83 V and its nominal voltage 1.5 V [26]. The energy density of an R6 sized battery with spirally wound electrodes is 450 mWh/cm^3 at a discharge rate of 8 mA.

At very low currents (0.4 mA and below) the discharge curve of the R6 sized battery exhibits two voltage plateaus according to Figure 36. The reason for this are the two discharge steps according to Reactions (6.57a) (first voltage plateau) and (6.57b) (second voltage plateau).

6.2.1.3.4. Batteries and Their Applications

At higher discharge rates (e.g., 60 mA and above), the discharge characteristics of the iron disulfide – lithium system change (see Figs. 37 A and B). Figures 37 A and B include a comparison with the LR6 battery (alkaline version of the MnO_2 – zinc system). Figure 37 A employs a 60 mA discharge current, Figure 37 B refers to a 800 mA discharge.

When comparing the two systems, it must be taken into account that the FeS_2 – Li battery uses spirally wound electrodes, i.e., a construction similar to Figure 32, which includes a safety vent and a PTC device. The LR6 battery, however, employs only a bobbin type construction (see Fig. 21). Because of this difference, the FeS_2 – Li battery offers a superior load capability, but at a significantly higher price.

Figure 37 A and B demonstrate that the FeS_2 – Li battery is especially attractive for high discharge currents: At 800 mA (21 °C, end-point voltage 0.9 V) the FeS_2 – Li battery delivers approx. 5 times more energy than the LR6. At 60 mA this energy factor drops to about 1.5 times.

The preferred application for this battery is therefore in the field of devices needing a high-rate power supply on a discontinuous basis like automatic cameras (film transport, flash light, etc.). Devices requiring a high-rate power on a continuous basis could technically also be operated. In this case, however, the use of a rechargeable battery system would certainly be more economic.

6.2.1.3.5. Prospects

The prospects of this battery are difficult to judge. They will depend on the number of applications that need this type of battery, and which cannot be operated satisfactorily by a cheaper 1.5 V battery system.

6.2.2. Batteries with Soluble Cathode

Systems with soluble cathode include the sulfur dioxide – lithium system (SO_2 – Li) with an organic electrolyte, the thionyl chloride – lithium system ($SOCl_2$ – Li) with an inorganic electrolyte, and the sulfuryl chloride – lithium system (SO_2Cl_2 – Li) with an inorganic electrolyte [104], [109].

6.2.2.1. Sulfur Dioxide – Lithium System

6.2.2.1.1. General

The sulfur dioxide – lithium system is a high-rate, high energy system. It was developed in

Figure 37. A) 60 mA-discharge performance of system FeS_2 – Li in comparison with the alkaline MnO_2 – zinc system during discharge of R6-sized batteries; B) 800 mA-discharge performance of system FeS_2 – Li in comparison with the alkaline MnO_2 – zinc system during discharge of R6-sized batteries [125]

the early 1970s by US companies essentially for space and military applications. It still is a special purpose battery that probably will never enter the commercial market. It also has not been proposed yet for International Standardization.

6.2.2.1.2. Electrochemistry

The discharge reaction (simplified) may be described by

Anode reaction

$$2\,Li \longrightarrow 2\,Li^{+} + 2\,e^{-} \tag{6.59}$$

Cathode reaction

$$2\,SO_2 + 2\,e^{-} \longrightarrow S_2O_4^{2-} \tag{6.60}$$

Overall reaction

$$2\,Li + 2\,SO_2 \longrightarrow Li_2S_2O_4 \tag{6.61}$$

A mixture of acetonitrile, lithium bromide, and sulfur dioxide serves as electrolyte.

A porous Teflon bonded carbon black layer serves as catalytic surface to promote Reaction (6.60) and in combination with a metal grid it also serves as current collector.

6.2.2.1.3. System-Immanent Properties

The open circuit potential of the sulfur dioxide – lithium system is approx. 3 V. Typical discharge voltages at a 10 to 20 h discharge rate are in the range 2.6 to 2.8 V.

Specific values for its energy content are

Energy density: 440 mWh/cm^3
Specific energy: 280 mWh/g

At ambient temperature the conductance of its electrolyte is $5 \times 10^{-2}\,\Omega^{-1}\,cm^{-1}$. It decreases only by 60% when the temperature is changed from + 50 °C to − 50 °C.

Reactions (6.59) and (6.60) have low reaction resistances such that the SO_2 – Li system exhibits an excellent low-temperature performance.

The good storage behavior results from the protective lithium dithionite layer on the surface of the lithium electrode formed by an initial reaction. Formation of this layer is also the reason for the initial voltage delay on discharge (see Figs. 28 and 39), which becomes more pronounced with increasing discharge current and decreasing temperature. The voltage delay can be eliminated by preconditioning with a short discharge at a higher rate [110].

Under normal conditions the SO_2 cathode material is gaseous. In order to have it in a liquid state it must be kept under sufficient pressure. At ambient temperature this pressure is 3 to 4 bar for an undischarged battery, at 100 °C it is about 20 bar. The system therefore needs an adequate battery design.

Because of its hazardous contents this battery must be used and handled extremely carefully [111]. Reference is also made to restrictions in transportation, shipment, and disposal of SO_2 – Li batteries and lithium batteries in general [1].

6.2.2.1.4. Batteries and Their Applications

The SO_2 – Li system is manufactured only in a cylindrical shape and assembled to multicell battery packs (including safety features like fuses etc.). It is predominantly used in military and noncommercial devices. A typical cylindrical battery construction is shown in Figure 38.

Figure 38. Cut-away view of a cylindrical SO_2 – Li battery [125]

Typical for this construction is the use of a hermetic glass-to-metal seal. It carries in its center the positive terminal, which is connected to the SO_2-electrode. The cylindrical cell case is connected to the negative pole, i.e., the lithium electrode. Integrated into the battery can is a rupture vent for safety reasons (opening pressure 20 to 35 bar, depending on product).

The electrode-pack consists of four rectangular strips, i.e.:

1) Lithium metal layer
2) Separator layer
3) Porous Teflon-carbon layer
4) Separator layer

These four layers are spirally wound to a cylindrical electrode-pack and inserted into the cell can. All layers are porous with the exception of the lithium electrode. Before cell closure they are soaked with electrolyte plus SO_2.

The discharge behavior of an 8 Ah SO_2 – Li battery at 21 °C is plotted in Figure 39 for different discharge currents. Typical is its flat discharge plateau and its initial voltage delay.

Figure 39. Discharge voltage vs. discharged capacity of an 8 Ah SO_2 – Li cylindrical battery at 21 °C for different discharge currents [110]

The discharge performance of the 8 Ah SO_2 – Li battery at different temperatures is illustrated in Figure 40. Selected temperatures are: Room temperature (RT), – 30 °C, – 40 °C and – 50 °C. In Figure 40 A the capacity is plotted as function of discharge current. In Figure 40 B the discharge voltage is plotted as function of discharge current. Figures 40 A and B demonstrate the outstanding low temperature behavior of the SO_2 – Li system.

6.2.2.1.5. Prospects

Since this system is predominantly used in military and professional applications, its prospects are difficult to judge. In any case, it will most likely not become a commercial consumer replaceable product but will continue to be the specialist for low-temperature/high-rate applications.

6.2.2.2. Thionyl Chloride – Lithium System

6.2.2.2.1. General

The 3.6 V thionyl chloride – lithium system ($SOCl_2$ – Li) is a high energy system. It is manufactured in two battery versions, i.e., low-rate and high-rate. Applications in the military and professional market are prevailing. The $SOCl_2$ – Li system has started to become also a consumer replaceable product. The IEC has meanwhile allocated system letter E to this system.

Figure 40. Discharge performance of an 8 Ah SO_2 – Li at different temperatures [110]; A) Discharge capacity versus current; B) Discharge voltage versus current.

Many types of this battery are available on the market. The preferred shapes are cylindrical and prismatic.

Because of their hazardous contents these batteries are not considered to be environmentally benign. Restrictions in handling, transportation, shipment and disposal have to be observed also for this system [1].

6.2.2.2.2. Electrochemistry

The reactions of the SO_2 – Li system (simplified) are described by:

Anode reaction

$$4\,Li \longrightarrow 4\,Li^{+} + 4\,e^{-} \tag{6.62}$$

Cathode reaction

$$2\,SOCl_2 + 4e^{-} \longrightarrow SO_2 + S + 4\,Cl^{-} \tag{6.63}$$

Overall reaction

$$4\,Li + 2\,SOCl_2 \longrightarrow S + SO_2 + 4\,LiCl \tag{6.64}$$

The electrolyte is composed of thionyl chloride, serving not only as cathode material but also as solvent for the conducting salt, which is usually lithium tetrachloroaluminate ($LiAlCl_4$).

Cathode reaction (6.63) is promoted by an active surface of a highly porous, electron conducting Teflon-bonded carbon-black structure, which represents the positive electrode. In addition, the carbon-black structure serves as current collector, and is connected to the positive terminal of the battery. It further functions as a repository for insoluble products of the discharge reaction like lithium chloride. At the end of discharge LiCl-precipitates may cover up the active carbon surface, finally terminating the discharge of a cathode-limited battery [112]. Since SO_2 dissolves very well in the electrolyte, its formation does not present any problems. It only leads to a slight increase of the battery's internal gas pressure. The formation of sulfur, however, may lead to a thermal runaway if substantial amounts should get into contact with the lithium electrode [104].

Figure 41. Cross-section of a bobbin-type $SOCl_2$ – Li cylindrical battery [110]

Figure 42. Discharge behavior of a R20-sized bobbin-type $SOCl_2$ – Li battery for different discharge resistances [110]

In contact with the thionyl chloride the lithium anode forms a protective LiCl film (SEI), which contributes to the system's excellent shelf life. Due to its low conductivity this LiCl film can cause a voltage delay at the beginning of a discharge (see Fig. 42). This voltage delay becomes more pronounced in the case of a preceding storage at elevated temperatures. Decreasing temperatures and increasing discharge currents increase the voltage delay. When continuing the discharge, the voltage recovers (cf. Fig. 28), due to a reduction of the thickness of the LiCl layer and thus in resistance.

6.2.2.2.3. System-Immanent Properties

According to the IEC [26] the thionyl chloride – lithium system has a maximum off-load voltage of 3.9 V and a nominal voltage of 3.6 V. Its standard discharge voltage is 3.4 V [26].

With large batteries, where the active material determines the battery volume, the following energy values may be obtained at ambient temperature and low-rate discharge:

Energy density: 900 mWh/cm^3
Specific energy: 460 mWh/g

The $SOCl_2$ – Li system has the highest specific energy of all primary battery systems and surpasses even that of the alkaline air – zinc system, which is about 360 mWh/g.

Its energy density is the highest of all lithium batteries.

Another advantage of this lithium system is that even a bobbin type construction permits moderate discharge rates up to a 50 h-discharge (example: a 5 Ah battery would carry a discharge current of up to 100 mA). Furthermore it has a wide temperature range within which it can be operated. The temperature range is determined by the electrolyte's freezing (– 110 °C) and boiling point (79 °C).

6.2.2.2.4. Batteries and Their Applications

All thionyl chloride – lithium batteries are characterized by a hermetic glass-to-metal seal of their positive terminal. *Button batteries* in 3 V standard dimensions [26], [33] do not exist.

Figure 43. Discharge voltage of a R20-sized (13 Ah) bobbin type $SOCl_2$ – Li battery vs. temperature for three different currents [110]

Cylindrical batteries are manufactured in two versions: with bobbin-type electrodes for low- and medium-rate applications, and with spirally wound electrodes for high-rate applications.

The *bobbin-type construction* is illustrated in Figure 41. The cathode is a highly porous body, made of Teflon-bonded carbon black. The cathode is in electronic contact with the current collector, which in turn is connected to the battery's

positive terminal. The positive terminal is part of the glass-to-metal seal. The separator between anode and cathode is made of nonwoven glass. The lithium foil is contacted to the inner surface of a nickel-plated steel or stainless steel can, and carries the negative terminal. Before battery closure the porous cathode and the separator are soaked with electrolyte, which includes the thionyl chloride.

Figure 44. Construction of a high rate $SOCl_2$ – Li battery, using spirally wound electrodes [125]

The discharge behavior of an R20-sized (13 Ah) cylindrical battery is presented in Figure 42. Characteristic is the initial voltage delay and the succeeding flat discharge plateau. The discharge voltage as function of temperature and three different discharge currents is shown in Figure 43.

The construction of an $SOCl_2$ – Li battery, using *spirally wound* electrodes is shown in Figure 44. This design includes several safeguarding devices like a vented top-shell, a fuse and a closing ball. These devices are designed to prevent an explosion of the battery even under extreme conditions including cell reversal. The discharge behavior of a high-rate R20-sized $SOCl_2$ – Li cell is plotted in Figure 45.

The capacity of a R20-sized $SOCl_2$ – Li high-rate battery as function of discharge current for three different temperatures is illustrated in Figure 46. Even at − 40 °C it still provides 4 Ah at a 200 mA discharge.

Figure 45. Discharge behavior of a high-rate R20 sized $SOCl_2$ – Li battery [110]

These high-rate cylindrical batteries are developed mainly for military applications and are assembled to multicell batteries. Military applications prevail also for the large high-capacity $SOCl_2$ – Li batteries (10 000 Ah and above), e.g., as standby power source [104] and for undersea applications [113].

Figure 46. Discharge capacity of an R20-sized $SOCl_2$ – Li high-rate battery for three different temperatures, endpoint-voltage 2.0 V [110]

6.2.2.2.5. Prospects

For many years $SOCl_2$ – Li batteries have been produced by manufacturers in the USA, Japan, and Europe. It is safe to predict that this system will continue to remain in the market. Cylindrical bobbin-type constructions with capacities in the range of 0.3 Ah to 3 Ah are preferred. Prevailing application is memory back-up in all kinds of electronic devices, including computers. In this application the $SOCl_2$ – Li battery has started to become a consumer replaceable product. The first E-system battery being included in the IEC Standard is a 6 V consumer replaceable memory back-up prismatic battery for personal

computers (battery designation 2EP3863). With the increasing electronic market the production volume of this kind of battery system will most likely increase as well. The prospects of batteries with spirally wound electrodes and/or extremely large capacities are difficult to judge.

6.2.3. Batteries with a Nonliquid Electrolyte

The attractive aspect of a nonliquid electrolyte in combination with a solid cathode and a solid anode is the option to construct batteries with a high energy content, however, without any gassing and leakage problems and relevant safety issues. This kind of battery system should furthermore offer the ability to be operable over a wide range of environmental conditions (temperature, pressure, and acceleration). These options have been and still are the impetus for extensive research and development work.

6.2.3.1. Polymer and Solid Electrolyte Systems

The term *polymer electrolyte* can be applied to a broad family of ion-conducting materials [114]. The ionic conductivities of polymer electrolytes at room temperature are typically by a factor 100 to 1000 lower than those of liquid electrolytes. This high specific resistance, however, can largely be compensated by thin-electrolyte-film techniques. Another unique aspect of the polymer electrolyte is that it represents a flexible film of a polymer matrix and an ionic salt complexed into this matrix.

The focus of polymer research and development has largely been on polyether-based solvent-free systems for lithium *rechargeable* batteries [114]. For *primary* battery systems preference has been given to solid electrolytes.

A large variety of *solid electrolyte systems* were studied in the past [115], while new ones are subject of research and development [116]. Solid electrolytes for battery application generally need to have a high ionic conductivity. High ionic conductivities, however, are only provided by solid electrolytes with monovalent ions as charge carrier, as for example, lithium, sodium, silver, potassium, or rubidium. Multivalent ions offer the advantage of a larger charge transfer, however, they exhibit a much lower mobility and thus a lower conductivity because of their strong electrostatic interactions with the crystal lattice. Optimal conductivity is achieved in a lattice with an ion that is neither too big nor too small to fit the available pathways in the lattice [117].

At room temperature the conductivity σ of solid electrolytes covers a range of

$$10^{-0.5}\,\Omega^{-1}\,\mathrm{cm}^{-1} \leq \sigma \leq 10^{-7}\,\Omega^{-1}\,\mathrm{cm}^{-1}$$

The temperature dependence of the conductivity σ of a given ion conductor follows mostly the Arrhenius equation

$$\log\sigma = H - A/T \tag{6.65}$$

where T is the absolute temperature, H and A being specific constants for a given solid electrolyte. When changing the temperature from 25 °C to, e.g., 200 °C the conductivity σ may increase by several orders of magnitude [116], depending on the type of ion conductor. A sufficiently high ionic conductivity of a solid electrolyte is a requirement for a practical battery. It is, however, not the only aspect that must be observed. Of practical interest are electrolyte systems offering in addition the option to compose a battery system of high voltage and a high energy density. This requirement is unfortunately not fulfilled for silver- and copper-ion conductors such as Ag_4RbI_5 and $Cu_{16}Rb_4I_7Cl_{13}$, with extraordinarily high ionic conductivities of the of order $10^{-0.5}\,\Omega^{-1}\,\mathrm{cm}^{-1}$.

The prospects of lithium, sodium, or potassium conductors are much better in terms of energy densities, as shown by the theoretical values given in Table 12. These values are based on a metal – I_2 system [115].

From Table 12 it is evident that Li-, Na-, or K-based ionic conductors are the preferable candidates for practical solid electrolyte batteries. Consequently research and development has been and still is focussed on relevant ion conductors. In the attempt to realize a fast sodium conductor GOODENOUGH was successful in developing a structure with the formula $Na_3Zr_2PSi_2O_{12}$, which is named Nasicon [118]. At 25 °C its conductivity is approx. $10^{-2.5}\,\Omega^{-1}\,\mathrm{cm}^{-1}$. With Nasicon GOODENOUGH contributed to the understanding that high ionic mobility requires the existence of interconnected spaces of partially occupied lattice sites.

Table 12. Theoretical values for open circuit potential U^0 and energy density for metal – I_2 systems based on some monovalent anode metals

Anode metal	U^0, V	Energy density, Wh/cm^3
Li	2.8	1.9
Na	3.0	1.6
K	3.4	1.3
Cu	0.7	0.59
Ag	0.7	0.51

Present lithium ion conductors have *total conductivities* in the range $10^{-3}\,\Omega^{-1}\,cm^{-1}$ to $10^{-7}\,\Omega^{-1}\,cm^{-1}$ [116]. Their *bulk conductivities* may be higher by two orders of magnitude. Of concern is the fact that only a few compounds of presently known lithium-ion conductors show thermodynamic stability in contact with elemental lithium, i.e., stability of the interface electrode – electrolyte. Because only thin-film solid electrolytes can be employed, a high specific electronic resistance is required to avoid self-discharge. For a practical system the specific electronic resistance must be in the range 10^{12} to $10^{14}\,\Omega\,cm$, which is an additional requirement a solid lithium-ion conductor must comply with.

For above reasons fast lithium-ion conductors may not always be the best choice, unless they also provide thermodynamic stability and a high specific electronic resistance.

6.2.3.2. The LiI(Al_2O_3) Solid Electrolyte System

A solid electrolyte system that constitutes a good compromise on the above requirements is the LiI(Al_2O_3) electrolyte. In combination with certain cathode materials such as $PbI_2 + S$, $PbI_2 + PbS$, and $TiS_2 + S$ different solid-state battery systems were developed in the 1980s by DURACELL and made available for commercial use. Later on, however, the production of the LiI(Al_2O_3) electrolyte system was discontinued.

The battery was designed in a circular disk configuration as shown in Figure 47, having a diameter of about 29 mm and a height of 2.5 mm (version 1), or 5.8 mm, respectively (version 2), which was a 2-cell-in-series arrangement [119]. The thickness of the electrolyte (d) is about 0.2 mm. During discharge the partial molar volume of the active materials decreases (valid for all lithium systems). To avoid any loss of contact between anode, electrolyte and cathode during discharge they must be kept under pressure. This is done by a wave spring (k).

Figure 47. Cross section of a Li – LiI(Al_2O_3) – PbI_2,PbS solid state battery [125]

Properties of the Single-Cell Battery.

U^0: 1.9 V
Capacity: 350 mAh
Energy density: 445 mWh/cm^3
Specific energy: 920 mWh/g

There is no loss of capacity after storage for one year, even at a storage temperature of 60 °C. The battery can withstand temperatures up to 200 °C [119].

6.2.3.3. The Lithium – Iodine System

6.2.3.3.1. General

The lithium – iodine system is only commercially available solid electrolyte battery system. Its development dates back to the early 1970s. Batteries of this kind are mainly produced in the USA (Catalyst Research Corporation, Wilson Greatbatch, Medtronic). Because of its high reliability in providing low power for a long time, the system has become a power source for heart pacemakers.

6.2.3.3.2. Electrochemistry

The basic reaction of the Li – I_2 system is described by Equation (6.66)

$$Li + 1/2I_2 \longrightarrow LiI \quad (6.66)$$

The reaction product is lithium iodide. It is formed as soon as the lithium surface is contacted by iodine. Lithium iodide constitutes the system's SEI.

In order to discharge the nonconducting iodine it must be mixed with an electronic conductor. In present commercial batteries poly-2-vinylpyridine (P2VP) is used as electron conducting medium. Thus the system may be designated by $Li - LiI - I_2(P2VP)$.

Its electrochemical reactions are:

Anode reaction

$$2\,Li \longrightarrow 2\,Li^+ + 2\,e^- \quad (6.67)$$

Cathode reaction

$$2\,Li^+ + 2\,e^- + P2VPnI_2 \longrightarrow P2VP(n-1)\,I_2 + 2LiI \quad (6.68)$$

Overall reaction

$$2\,Li + P2VPnI_2 \longrightarrow P2VP(n-1)\,I_2 + 2\,LiI \quad (6.69)$$

Its reaction product LiI is identical to that of Reaction (6.66).

6.2.3.3.3. System-Immanent Properties

A unique feature of the system is that its reaction product LiI serves simultaneously as separator and as lithium-ion conductor. Lithium iodide is a solid electrolyte, having a conductivity at the order of $10^{-7}\,\Omega^{-1}\,cm^{-1}$. On discharge the LiI-layer grows in thickness proportional to the capacity discharged from the battery, i.e., its internal resistance increases constantly during discharge.

The system's open circuit voltage is approx. 2.8 V. Depending on battery type and capacity (1 to 2.5 Ah) its practical energy density ranges from 0.7 to 0.99 Wh/cm^3, and may be obtained at a discharge current density of $1-2\,\mu A/cm^2$.

As typical for all lithium systems the partial molar volume of the $Li - LiI - I_2(P2VP)$ system decreases during discharge (in theory by 15 % for a complete discharge). Being a kind of viscous liquid, $I_2(P2VP)$ can adapt itself better to the system's volume changes than a solid.

6.2.3.3.4. Batteries and Their Applications

Pacemaker batteries are available from several companies. Figure 48 illustrates the construction of a pacemaker battery made by Wilson Greatbatch. Depending on type, its volume ranges from 3 to 6 cm^3. The battery thickness ranges from 5 mm to 10 mm.

Figure 48. Cutaway view of a pacemaker battery [110]

Figure 49. Cutaway view of a lithium – iodine button battery [110]

Typical discharge currents in application are of the order of 20 μA. Depending on battery capacity, the discharge time may be as long as 10 years. For discharge currents of 10 μA and below, the voltage under load drops about linearly with time down to approx. 2.5 V, mainly because the LiI layer increases in thickness. At the end of discharge nonohmic resistances come into play until the voltage drops abruptly. At high discharge rates nonohmic resistances influence the discharge curve from the beginning.

When looking for new applications the possibility was studied to operate wrist watches continuously for a ten years period by a suitable lithium – iodine battery. Figure 49 illustrates such a battery construction.

The discharge characteristic of a 650 mAh button battery is shown in Figure 50. Although

technically feasible, a commercial market for wrist watches with lithium-iodine batteries could not be realized.

Figure 50. Discharge voltage vs. time for a 650 mAh lithium iodide button battery for different loads [110]

6.2.3.3.5. Prospects

The commercial market for present solid-state battery systems is limited because of their high internal resistance. If reduced by three to four orders of magnitude, new applications may evolve. The only commercial market for the lithium – iodine system is presently the heart pacemaker market, which also accepts the high price for the battery.

6.3. Reserve Batteries

6.3.1. Principles

A reserve battery is a primary battery system that only after activation provides electrical energy to operate a specific electric device for a predetermined period of time, which may range from seconds to weeks. The time at which the electrical power is needed is usually unknown (like a case of emergency). The waiting period until the reserve system is activated, may be ten years and more.

The battery employed is usually a high-rate system. Its self-discharge would not be negligible if kept active over a long period of time. This is especially true when the system is exposed to elevated temperatures during standby. But also at normal to low temperatures the overall reliability of the system may decline if kept active over several years. Therefore for reserve batteries preference is given to systems, that are kept inactive during standby.

Each electrochemical system consists of three key components, i.e., cathode, electrolyte, and anode. The reserve battery is characterized by the fact that one of these key components is separated from the other two. A preferred key component is the electrolyte (cf. Section 6.3.1.1).

Shortly before the electrical energy is needed, the activation is carried out by removing the separation between the electrolyte and the electrodes. The activation of the system occurs by a physical process, in consequence of which the electrolyte enters the space between anode and cathode while intimately contacting the total surface of both electrodes. In the simplest case the addition of the electrolyte is done by hand. Depending on the specific conditions, however, the activation mechanism may be more complex (cf. Section 6.3.1.1.2).

Another kind of electrolyte activation employs a solid-state electrolyte that only becomes an ion conductor if heated up to its melting point. During standby the solid state electrolyte is a nonconductor. This group of systems is known as thermal batteries (cf. Section 6.3.1.2).

In addition, a battery can be kept inactive during standby if its electrochemically active materials are stored separately. These materials should preferably be in the liquid or gaseous state to facilitate distribution and transport to the battery's electrodes in the case of activation. Reserve batteries that store gaseous or liquid cathode and/or anode materials during standby in separate containers are in principle similar in function to fuel cells [121]: The system starts to work as soon as the active material(s) are released to the relevant electrodes. In this sense the air – zinc system could also be counted to the group of reserve systems, since it complies with the afore mentioned criteria: It starts working as soon as its air access is opened (cf. Section 6.1.3.4).

6.3.1.1. System Activation with Liquid Electrolyte

6.3.1.1.1. Water-Activated Batteries

An example of this group of systems are the *water-activated metal chloride – magnesium batteries* (cf. Section 6.1.2). Their activation is

carried out by manually opening their water access holes. Properties and typical applications for this type of battery are described in Section 6.1.2.

6.3.1.1.2. KOH Activated Batteries

Because of its high energy density and high rate capability the silver oxide – zinc system is well suited for reserve battery systems (cf. Section 6.1.3.2). It may be based on monovalent or divalent silver oxide or mixtures thereof. In the simplest case the activation of this system is carried out manually by filling the electrolyte (KOH) into the battery. Alternatively, dry KOH pellets may be stored inside the battery. In this case only water must be added, having the beneficial effect that the heat, generated in consequence of KOH-dissolution, improves the battery performance.

Manually-Activated Batteries. A broad range of 1.5 V silver oxide – zinc battery modules for manual activation exists, predominantly used in military applications. The batteries cover a capacity range from 1 to 775 Ah at a weight from 25 g to 4.4 kg.

Gas Activation. A more sophisticated activation system for a multicell battery arrangement is shown in Figure 51. As can be realized from the drawing, the activation is carried out by activating the gas generator. The generated gas forces the piston to move, while pressing the electrolyte into the multicell battery arrangement, which activates the battery.

Systems of this kind are used for automatically activated silver oxide – zinc reserve batteries, for military (e.g., missiles) and space applications. Their characteristics cover following ranges:

Voltage: 26 – 50 V
Capacity: 0.8 – 20 Ah
Current: 2 – 80 A
Power: 260 W – 2.24 kW
Energy: 20 – 600 Wh

Torpedo batteries based on the silver oxide – zinc system have an energy content of 20 to 25 kWh at a power output of approx. 20 kW.

Figure 51. Schematic drawing of an activation system with piston activator [12]

Figure 52. Vanadium pentoxide – lithium reserve battery ([125], Fig. 21.3)

6.3.1.1.3. Ampoule-Type Batteries

The unique feature of this type of battery construction is a glass ampoule, serving as electrolyte reservoir, which is arranged within the battery. The electrolyte is released (activation) as soon as the ampoule brakes due to mechanical force acting from outside.

This construction is preferred for small single-cell reserve batteries. The principle, however, is also used in multicell battery arrangements. The electrolyte used depends on the electrochemical system employed.

Vanadium Pentoxide – Lithium System (Fig. 52). In the vanadium pentoxide – lithium system (V_2O_5 – Li) the electrolyte is separated from the electrodes by a glass ampoule. Activation is carried out by an external force

that hits the battery's bottom, thus braking the glass ampoule inside the can. Under this condition the electrolyte is released and soaked up by the electrode – separator arrangement, and the battery is thus activated (voltage range during discharge: 3.4 – 2.3 V; capacity range: 100 – 500 mAh, depending on battery). Depending on manufacturer, the design and size of the battery varies.

Figure 53. Cutaway view of a thionyl chloride – lithium single-cell reserve battery [110]

Thionyl Chloride – Lithium and Sulfur Dioxide – Lithium Systems. Figure 53 presents a cutaway view of a thionyl chloride – lithium single-cell reserve battery. Its construction is practically identical to that of Figure 52. Identical is also the battery's mode of activation being carried out by braking the ampoule by an external force.

However, there is a distinct difference between both, because thionyl chloride is not only the solvent of the electrolyte, which includes the conducting salt, but is simultaneously the cathode material. Thus, both electrolyte and cathode material are encapsulated in the ampoule. Similar arrangements exist for SO_2 – Li single-cell reserve batteries, which also encapsulate SO_2, the cathode material and the system's electrolyte, in an ampoule before activation.

Spin-Activated Battery. A variant of the above mechanism is used in the spin-dependent reserve battery. In this case the external force is represented by high spin forces as provided by artillery projectiles. The electrode stack of this battery consists of electrodes of an annular configuration with an electrolyte-filled ampoule in its center. Upon firing of the gun, the ampoule is torn apart and the electrolyte is released and activates the battery.

6.3.1.1.4. Battery Activation by Ammonia

This battery construction contains an electrolyte compartment, which is filled with ammonia, instead of an ampoule. It is separated from the cell stack by a seal.

A multicell ammonia reserve battery of this type is shown in Figure 54. When activating the gas generator (not shown) the membrane of the NH_3-reservoir is forced down, including the lance, that punctures the seal of the battery compartment (see right-hand figure). Under this condition the ammonia is injected into the battery compartment and distributed via its manifold system to the cell stack. The cell stack contains NH_4SCN and KSCN in a dry form. They are dissolved in ammonia, such that the electrolyte obtains its final composition within the electrode stack. About 200 ms after activation the battery is ready for use.

The liquid ammonia reserve battery employs ammonia in combination with ammonium thiocyanate (NH_4SCN) and potassium thiocyanate (KSCN) as electrolyte [122]. Ammonia offers several advantages like a low viscosity and in combination with above thiocyanates a high conductivity in a wide temperature range (– 55 – + 74 °C). The low viscosity of ammonia facilitates its distribution within a multicell battery arrangement. Different electrochemical systems are used like the 3 V – (PbO_2 – NH_4SCN – Mg)- or the 2.3 V – (S – KSCN – Mg)-system.

6.3.1.2. Thermal Batteries

6.3.1.2.1. General

Thermal batteries also belong to the group of electrolyte-activated primary reserve batteries. Their activation, as well as their cell and battery components differ, however, significantly

Figure 54. Liquid ammonia multicell reserve battery, activation by a pyrotechnic gas generator (capacity approx. 430 mAh, voltage 9 V) Alliant Techsystems, USA ([125], Fig. 20.4)

from ambient-temperature systems, such that they form a group of their own [123].

The unique feature of a thermal battery is the electrolyte which is an inorganic salt and a nonconducting solid under ambient temperature conditions. It is in direct contact with the system's anode and cathode. When the solid electrolyte is heated up to its melting point, i.e., activated, it becomes a very fast ion conductor and the electrochemical system is active and ready to provide electric energy.

The heat source to melt the electrolyte is a pyrotechnic material being integrated into the battery and activated by application of an energy impulse from an external source to a built-in initiator, which ignites the pyrotechnic. After activation, the temperature rises above the melting point of the electrolyte of 352 °C (eutectic mixture of LiCl + KCl) but remains below the melting point of the active materials (anode and cathode). Thermal insulation of the battery is important. The external temperature of the battery is at its peak at least 230 °C. If the temperature of the electrolyte falls below 352 °C the battery stops working. A schematic drawing of a thermal battery is shown in Figure 55.

General characteristics of thermal batteries are:

1) Long shelf life in a nonactivated state (> 10 a)
2) Provision of electric power in less than a second after activation
3) High reliability
4) Insensitivity to mechanical shock, acceleration, and vibration
5) Active life up to 1 h but typically less than 10 min

6.3.1.2.2. Systems

A wide variety of systems have so far been subject of research and development. The following *cathode materials* have been tested: Calcium chromate ($CaCrO_4$), potassium dichromate ($K_2Cr_2O_7$), potassium chromate (K_2CrO_4), lead chromate ($PbCrO_4$), metal oxides (V_3O_5, WO_3) and sulfides (CuS, FeS_2, CoS_2). Calcium, magnesium, lithium, and alloys thereof are in use as *anode materials*. Most thermal battery systems employ an eutectic mixture of lithium chloride and potassium chloride (*mp* 352 °C) as electrolyte.

Figure 55. Schematic drawing of a thermal battery [110]

Of all systems investigated so far preference has been given in recent years to the iron disulfide – lithium system because of its stable and predictable chemistry at high temperatures. The calcium chromate – calcium system has been attractive for a long time because of its higher average operating cell voltage (2.4 V compared to 1.9 V). New promise for more high temperature stability and active battery lives of above 1 h is offered by the CoS cathode [124].

6.3.1.2.3. Pyrotechnic Heat Sources

Two different types of heat sources are in use, *heat paper* and *heat pellets*.

Heat paper has the composition Zr – $BaCrO_4$ and is manufactured from zirconium powder and $BaCrO_4$. The mix together with water is formed into a paper by a paper-making process, cut into parts and dried. In a dry state it must be handled very carefully to avoid its ignition.

Heat pellets are made by cold pressing a dry blend of iron powder (Fe in excess) and potassium perchlorate ($KClO_4$). Heat pellets provide a heat content of approx. 1 kJ/g. After combustion the heat pellet remains an electronic conductor, serving as intercell connector.

6.3.1.2.4. Battery Construction

Figure 56 illustrates an exploded view of a thermal cell including heat pellets on the cell's top and bottom. The top-cover contains four metal-to-glass terminals: Two for the battery (+ and −) and two for the ignition of the heat pellets.

Figure 56. Exploded view of a thermal battery (schematic) [110]

Different cell constructions are in use. The *cup cell* uses two heat pads on its outside, two cathodes, two electrolyte pads and in the middle a "two-sided" anode (Fig. 57 A). The *pellet cell* construction consists of the anode (e.g., Ca – Fe bimetal) and a two-layer pellet, i.e., cathode – electrolyte plus a heat pellet on the cathode's side (Fig. 57 B).

6.3.1.2.5. Batteries

The *iron disulfide – lithium batteries* have the following characteristics and cover the following ranges:

Nominal voltage: 25 – 315 V
Current: 1 – 17 A
Peak power: 138 W – 3.6 kW
Average life: 35 – 900 s
Weight: 270 g – 6.62 kg
Volume: 92 cm^3 – 3.12 L

The *calcium chromate – calcium batteries* have the following characteristics and cover the following ranges:

Nominal voltage: 28 – 42 V
Current: 1.2 – 3 A
Peak power: 34 – 125 W
Average life: 25 – 150 s
Weight: approx. 310 g
Volume: approx. 120 cm^3

Figure 57. Thermal battery, multicell arrangements
A) Cup cell construction; B) Pellet cell construction ([125], Fig. 22.7)

6.3.2. Prospects

Reserve batteries will remain to be special-purpose batteries. They are not available on the commercial market. Their main use will continue to be in the field of military and space appliances, apart from rescue systems. Further developments are difficult to judge.

More information on reserve batteries is given in [125].

7. Secondary Batteries

Secondary batteries are genuine storage systems, since their discharging reaction can be reversed and the battery recharged. The efficiency of the storing process is limited for two reasons:

1) Kinetic parameters cause polarization that decreases the voltage during discharging, and increases it during charging. The gap between charging and discharging voltage characterizes the energy loss.
2) Secondary reactions that occur in parallel may consume a portion of the current applied for charging.

7.1. Batteries with Aqueous Electrolyte

Most of the commercially used batteries are based on aqueous electrolytes such as dilute solutions of sulfuric acid (H_2SO_4) and potassium or sodium hydroxide (KOH or NaOH, respectively). The main advantage of these electrolytes is their high conductivity.

Table 13 shows characteristic data of aqueous battery systems that are of technical interest. The values in the last two columns are only approximate data of comparison, since they largely depend on the design of the individual battery.

Redox and air – metal batteries that also use aqueous electrolyte, are treated in Section 7.1.3.3 and in Sections 6.1.1.2, 6.1.3.4, 7.1.3.4, respectively. The manganese dioxide – zinc system which has a certain rechargeability is treated in Section 6.1.3.1. A number of further electrode combinations that operate in aqueous electrolyte are known, but they have no technical importance.

Reactions of the Electrolyte. The main disadvantage of aqueous electrolytes is the comparatively low decomposition voltage of water of 1.23 V. As soon as the cell voltage exceeds this value, the water in the electrolyte is decomposed into hydrogen and oxygen according to:

$$H_2O \longrightarrow H_2 + 1/2 \cdot O_2$$

[Water decomposition]Water decomposition is the combination of two electrochemical reactions:

The evolution of oxygen at the positive electrode by oxidation of O^{2-} ions according to

$$H_2O \longrightarrow 1/2\,O_2 + 2\,H^+ + 2\,e^- \text{ for acidic media}$$

or

$$2\,OH^- \longrightarrow 1/2\,O_2 + H_2O + 2\,e^- \text{ for alkaline media}$$

and the evolution of hydrogen, by reduction of H^+ ions at the negative electrode:

Table 13. Rechargeable battery systems with aqueous electrolyte. Lead – acid systems use dilute sulfuric acid as electrolyte, the others dilute KOH or occasionally NaOH. Performance data refer to a single cell.

	System	Open circuit voltage, V/cell	Stored energy		
			Theory,	Practice,	
			Wh/kg	Wh/kg	Wh/kg
1	Lead – acid	2 [a]	161	20 – 50	60 – 100
2	Nickel hydroxide – cadmium	1.32 [b]	240	20 – 50	40 – 60
3	Nickel hydroxide – hydrogen	1.34 [b]	387	50 – 60	50 – 70
4	Nickel hydroxide – metal hydride	1.34 [b]	≈ 300 [c]	50 – 80	100 – 150
5	Nickel hydroxide – iron	1.3 [b]	267	40 – 60	80 – 120
6	Nickel hydroxide – zinc	1.73 [d]	341	80 – 100	140 – 180
7	Silver oxide – zinc	1.8/1.6 [e]		70 – 120	130 – 220
8	Silver oxide – cadmium	1.4 [f]	310	50 – 75	90 – 140

[a] Open circuit voltage depends on acid concentration.
[b] Uncertain value on account of peculiarities of the nickel hydroxide electrode; nominal voltage 1.2 V/cell.
[c] Depends on the alloy, used for hydrogen storage.
[d] Nominal voltage 1.6 V/cell.
[e] Two plateau discharge (cf. Fig. 102).
[f] Nominal voltage 1.2 V/cell.

$$2\,H^+ + 2\,e^- \longrightarrow H_2 \text{ for acidic media}$$

or

$$2\,H_2O + 2\,e^- \longrightarrow 2\,OH^- + H_2 \text{ for alkaline media}$$

The equilibrium voltage of water decomposition is $U^o = 1.229$ V. When the cell voltage exceeds this value, water is decomposed according to the above equations.

The reversible heat effect of water decomposition is (cf. Eq. 3.1)

$$Q_{\mathrm{rev}} = T \cdot \Delta S = T \cdot \Delta H - \Delta G = 48.6\mathrm{kJ}$$

This is 20.5 % of the free reaction enthalpy, and, according to Equation (3.21), the calorific voltage of water decomposition is

$$U_{\mathrm{cal}} = 1.229\,\mathrm{V} + 0.252\,\mathrm{V} = 1.481\,\mathrm{V}$$

In regard to battery practice, the reversible heat effect lowers heat generation during overcharging since the difference $U - U_{\mathrm{cal}}$ is smaller than $U - U_{\mathrm{o}}$ (see Eq. 3.29).

Internal Oxygen Cycle. Valve-regulated lead – acid batteries (VRLA batteries), sealed nickel – cadmium, and nickel – metal hydride batteries are characterized by the internal oxygen cycle: Oxygen that is generated during charging or overcharging at the positive electrode is subsequently reduced at the negative electrode by reversal of the above O_2 producing equations. Oxygen generation at the positive electrode is thus counterbalanced at the negative electrode, and the created oxygen cycle absorbs the overcharging current that otherwise would decompose water into hydrogen and oxygen.

To achieve the required fast transport of oxygen, the electrolyte must be immobilized, i. e., soaked in a mat of fine fibers of polyamide or polyethylene in alkaline batteries, or in an absorbent-glass mat (AGM) in lead – acid batteries (cf. Section 7.1.1.10). The amount of electrolyte must be limited so that larger pores of the matrix remain open and provide space for fast diffusion of oxygen in the gaseous phase. In lead – acid batteries, the electrolyte can alternatively be fixed as a gel by addition of SiO_2. In the gel cracks are formed which also provide open space.

In both cases, the hindrance of the oxygen transport to the negative electrode is nearly nullified, since oxygen transport occurs about 10^6 times faster through the gaseous phase than via dissolution through the electrolyte, and only a thin wetting layer on the surface of the negative electrode has to be penetrated by dissolved oxygen. Thus, nearly all oxygen that is evolved at the positive electrode, reaches the surface of the negative electrode, and is there reduced by reversal of the above oxygen evolution reaction.

Such an ideal situation can only be achieved in nickel – cadmium and nickel – metal hydride batteries that can virtually be sealed. In valve-regulated lead – acid batteries, hydrogen evolution and grid corrosion occur as unavoidable secondary reactions as shown in Fig. 70.

7.1.1. Lead – Acid Batteries

The lead – acid battery is the most important electrochemical energy storage system. Its storage capacity is moderate compared to other electrochemical systems, but the battery has several features that make it especially suited for standby applications. In addition, its comparatively low price is one reason for its widespread use.

7.1.1.1. Charge/Discharge Reactions

The electrode reactions of the lead – acid system are both based on lead, but in different states of oxidation, namely Pb^{2+} and Pb^{4+}.

During discharge, Pb is oxidized to Pb^{2+} at the negative electrode

$$Pb \leftrightarrow Pb^{2+} + 2\,e^-$$

and Pb^{4+} is reduced to Pb^{2+} at the positive electrode

$$Pb^{4+} + 2\,e^- \leftrightarrow Pb^{2+}$$

The double arrow in both equations indicates that these reactions can be reversed (under addition of energy). This reversion describes the charging process.

These equations have to be completed, because the solubility of Pb^{2+} ions in sulfuric acid is extremely low ($\approx 10^{-6}$ mol/L), and any Pb^{2+} formed beyond this concentration is precipitated as $PbSO_4$. Furthermore, in the positive electrode, Pb^{4+} ions do not occur in the free form, but as lead dioxide (PbO_2). When both facts are observed, the completed reactions are:

at the negative electrode:

$$Pb + H_2SO_4 \leftrightarrow PbSO_4 + 2\,H^+ + 2\,e^-$$

and at the positive electrode:

$$PbO_2 + H_2SO_4 + 2\,H^+ + 2\,e^- \leftrightarrow PbSO_4 + 2 \cdot H_2O$$

Summation of the two electrode reactions results in the cell reaction:

$$Pb + PbO_2 + 2\,H_2SO_4 \leftrightarrow 2\,PbSO_4 + 2\,H_2O$$

When the lead – acid battery is discharged, lead (Pb) and PbO_2 are converted into $PbSO_4$. In other words, during discharge sulfate ions from the electrolyte are absorbed in the electrodes. When the battery is charged, sulfate is released from the electrodes. The reactions at both electrodes include the dissolved state, i.e., the reacting species are dissolved in the course of the reaction. The new chemical compounds, formed by the reactions, are precipitated again as solid matter. About 8 g of substance have to be dissolved per drawn or charged ampere hour.

Detailed examinations revealed that lead dioxide does not always correspond exactly with the stoichiometric formula PbO_2, but some (small) deviations are observed that indicate that the true formula reads $PbO_{1.99}$.

In the concentration range used in batteries, dilute H_2SO_4 is dissociated mainly into H^+ and HSO_4^- ions. Only about 1 % of the H_2SO_4 molecules dissociate into $2\,H^+$ and SO_4^{2-}. In consideration of this dissociation the cell reaction can be written as

$$Pb + PbO_2 + 2\,H^+ + 2\,HSO_4^- \leftrightarrow 2\,PbSO_4 + 2\,H_2O$$

which describes the actual situation more adequately. The free enthalpy of this reaction is $\Delta G = -372.6$ kJ. When this value is inserted into Equation (3.2) the standard value of the equilibrium voltage results: $U^{o,s} = 1.931$ V.

This standard value applies when the activities (effective concentrations) of the soluble components of the reaction, namely H^+, HSO_4^-, and H_2O amount to 1 mol/L. This is approximated by an acid concentration of 1.083 mol/L (≈ 10 wt % or a density of 1.066 g/cm^3). The dependence of the equilibrium voltage on concentration is given by the Nernst equation, Equation (3.5):

$$U^o = 1.931 + 0.0592 \cdot \log \frac{a_{H^+} \cdot a_{HSO_4^-}}{a_{H_2O}}\,\mathrm{V}$$

The equilibrium cell voltage depends only on the acid concentration. It is independent of the present amount of lead, lead dioxide, or lead sulfate, as long as all three substances are available in the electrode. The result of this equation is plotted in Figure 58.

Figure 58. Equilibrium cell voltage of the lead – acid battery referred to acid density in g/cm^3 and acid concentration in wt % H_2SO_4

In battery practice, usually the following approximation is used:

Equilibrium cell voltage = acid density (in g/cm^3 or kg/L) + 0.84

Figure 58 shows that the calculated curve and the approximate formula coincide quite well.

Actually not the true equilibrium voltage but only the open circuit voltage can be measured with lead – acid batteries. Due to the unavoidable secondary reactions of hydrogen and oxygen evolution and grid corrosion, mixed potentials are established at both electrodes, which are somewhat different from the true equilibrium potentials (cf. Fig. 9). But the differences are small and can be neglected.

Since H_2SO_4 participates in the electrode reaction, the electrolyte becomes more diluted during discharge and is reconcentrated during charge. As a consequence, the discharge voltage does not remain constant even at low discharge rates. Furthermore, the conductivity of the acid varies when the battery is charged or discharged, and in cold climates the freezing point of the electrolyte may be reached during discharge. Then the resistance of the electrolyte is significantly increased and further discharging as well as subsequent charging are hindered. On the other hand, the changing acid concentration provides a tool to determine the state of charge.

The temperature coefficient of the equilibrium voltage is according to Equation (3.6):

$$\frac{\mathrm{d}U^{\circ}}{\mathrm{d}T} = 0.23\,\mathrm{mV/K}$$

This temperature coefficient is strictly valid only for standard condition, because the thermodynamic parameters depend on acid concentration as well as on temperature [126]. On the whole, the temperature coefficient of the equilibrium voltage is so small that it can be neglected in practice.

7.1.1.2. Secondary Reactions

The lead – acid battery is an unstable system in two respects:

1) Its cell voltage of 2 V is far above 1.23 V, the decomposition voltage of water.
2) The high potential of the positive electrode oxidizes all metals, usually applied as current conductors. Lead can be used, since on its surface a layer of lead dioxide is formed by corrosion that protects the underlying metal. But this layer is not totally stable and a certain current is continually required to reestablish the protecting layer. Corrosion is so gradually progressing into the metal that forms the grid and the conducting elements.

As a consequence, hydrogen evolution, oxygen evolution, and grid corrosion are unavoidable secondary reactions in the lead – acid system.

Figure 59 illustrates the situation. The electrode potential is plotted on the *x*-axis, the range of the negative electrode on the left-, the range of the positive electrode on the right-hand side. The two hatched columns represent the equilibrium potentials of the negative and positive electrodes. Their dependence on acid concentration is indicated by the width of these columns. The potential difference of 1.23 V between the beginning of hydrogen and oxygen evolution marks the water decomposition voltage.

The *charging and discharging reactions* are represented by the broken curves. They are very steep, since these reactions are fast, even at a small deviation from the equilibrium potential.

Hydrogen evolution begins at an electrode potential of 0 V which is about 0.3 V above the open-circuit potential of the negative electrode. *Oxygen evolution* starts at 1.23 V which is about 0.5 V below the positive electrode potential. Thus, hydrogen and oxygen evolution already occur at the open circuit potential of the

Figure 59. Reactions occurring in lead – acid batteries vs. electrode potential. The rates of these reactions are indicated by current-potential curves

negative and positive electrodes, respectively, and at open circuit, gradual self-discharge of both electrodes is the result. In Figure 59, both reactions are represented by continuous curves. The gradual increase at their beginning indicates that these reactions occur slowly as long as the potential remains fairly close to the origin of the corresponding curve. When, however, this deviation from the equilibrium potential of the concerned gas evolution reaction exceeds a certain value, the two curves show a steep increase. This means that hydrogen as well as oxygen generation gain in volume enormously at a correspondingly low and high overvoltage or polarization referred to their equilibrium potential. For this reason, small gassing rates characterize the lead – acid battery at the usual standby voltage of about 2.25 V/cell, but heavy gassing is observed at a voltage that exceeds 2.5 V/cell.

Corrosion of the positive grid also is an electrochemical reaction. The corrosion rate is at its minimum at about 40 to 80 mV above the $PbSO_4/PbO_2$ potential. At an electrode potential below this minimum, corrosion increases due to destabilization of the protecting PbO_2 layer. Above this minimum, the corrosion rate follows the usual exponential increase with increasing electrode potential.

Corrosion gradually destroys the current conducting elements, but is also a water consuming reaction, since oxygen that is required for the reaction is taken from the electrolyte

$$Pb + 2\,H_2O \longrightarrow PbO_2 + 4\,H^+ + 4\,e^-$$

Corrosion is a complex reaction, influenced by a number of parameters. Not only "external parameters" like temperature, electrode potential and acid concentration are important, but also "internal parameters" like composition of the corroding alloy, metallographic structure and local distribution of the alloying additives (→ Corrosion).

Oxygen reduction, the reversal of oxygen generation, is possible in the acid electrolyte at an electrode potential below 1.23 V vs. SHE. It is a quick reaction at the potential of the negative electrode that is far below + 1.23 V, and oxygen is immediately reduced when it reaches the surface of this electrode. For this reason, the rate of this reaction is largely determined by the rate of oxygen transport and therefore does not depend on the potential of the negative electrode. Oxygen reduction forms a limiting current that is characterized by the horizontal curve in Figure 59.

In flooded batteries, the transport of dissolved oxygen through the electrolyte limits this reaction rate to very low values. In VRLA batteries, however, the immobilization of the electrolyte allows fast transport of oxygen by diffusion in the gas-filled space. As a consequence, the inter-

nal oxygen cycle (cf. Section 7.1) characterizes this battery type.

7.1.1.3. Self-Discharge

At open circuit, the secondary reactions form mixed potentials with the discharge reactions, according to Figure 9.

At the positive electrode, oxygen evolution and grid corrosion are compensated by discharge, i.e., the reduction of PbO_2 to $PbSO_4$.

At the negative electrode, hydrogen evolution and oxygen reduction are compensated by the oxidation of lead to $PbSO_4$. Since the supply of oxygen from the positive electrode is negligible at open circuit, in flooded lead – acid batteries the self-discharge rate of the negative electrode is largely caused by hydrogen evolution.

The self-discharge rates of positive and negative electrodes occur independently from each other. They depend markedly on the state of charge of the concerned electrode and are reduced with progressing discharge. Furthermore, an increase in temperature of 10 °C approximately doubles the self-discharge rate.

7.1.1.4. Heat Effects

The reversible heat effect, defined by Equation (3.19), amounts to $Q_{\mathrm{rev}} = 13.2$ kJ per formula conversion of the cell reaction.

Comparison with the value for ΔG (− 372.6 kJ) shows that the reversible heat effect is only 3.5 % of the amount of energy converted during charge or discharge. The positive sign means cooling during discharge, and additional heat generation when the lead – acid battery is charged. But only when the lead – acid battery is discharged at very low rates (duration of discharge > 10 h) slight cooling of the battery can be observed. Usually, the reversible heat effect is concealed by the Joule effect.

According to Equation (3.20), Q_{rev} can be expressed as a (fictive) voltage. Since $Q_{\mathrm{rev}}/2 \cdot F = 0.068$ V, the calorific voltage in lead – acid batteries is according to Eq. (3.21)

$$U\mathrm{cal} = U^{\mathrm{o}} - 0.068\,\mathrm{V}$$

For heat calculations, this reduced value has to be used instead of the equilibrium voltage.

The above calculated values for the reversible heat effect, the temperature coefficient, and the calorific voltage are strictly valid only for standard conditions; the values actually depend on acid concentration and temperature, but the deviations are rather small and their contributions so insignificant that the conclusions can be extended to the usual range of acid concentration and temperature.

During charging, heat generation due to decomposition of water is much higher than that of the charging reaction itself, since the calorific voltage U_{cal} of water decomposition is 1.48 V and thus much lower than the cell voltage. For this reason, the current share that is consumed by water decomposition generates much more heat than it would when it were used for charging the battery. Figure 60 is an example of the heat generation in a charging/discharging cycle of vented lead – acid batteries, usually applied in traction applications.

The voltage curve is shown at the top of the figure:

- A current-limited initial step of charging is followed by a constant-voltage period at 2.4 V/cell. Equalizing charging at constant current up to about 2.65 V/cell is the final step of this charging schedule.
- Discharge is assumed at constant current ($I_5 = 20$ A/100 Ah). The broken curve shows the calorific voltage, while the full line represents the actual discharge voltage.

The middle of the Figure shows the current and its distribution with respect to charging, water decomposition, and discharging.

- During the initial stage, practically only charging occurs. Only when the voltage approaches the 2.4 V level, the onset of water decomposition becomes noticeable.
- As long as the cell voltage remains at 2.4 V, gas evolution is maintained at a roughly constant rate (assuming that the potentials of the positive and negative electrodes do not change too much).
- During the equalizing step, nearly all the current is used for water decomposition on account of the progressively reduced charge acceptance.
- During discharge, water decomposition is neglected.

Figure 60. Charging/discharging cycle of a vented traction battery, a lead – acid battery with tubular positive plates (VARTA PzS), capacity 500 Ah.
Heat-generation values refer to 100 Ah of nominal current. The figures in the bottom part represent heat generation in total. The sum of the whole charging period amounts to 166 kJ/100 Ah.

At the bottom of Figure 60, the heat generation is drawn as blocks that represent average values for the corresponding sections of the charging/discharging processes. The distribution between reversible heat effect, charging, and water decomposition is marked by different patterns. The value above each block is the total heat generation in kilojoules.

- During the first stage of the charging process, gas evolution can be neglected. The main portion of heat is generated by the Joule effect, on account of the fairly high current. But the reversible heat effect also contributes noticeably to heat generation, since a large amount of active material is converted.
- When 2.4 V is reached, the current is reduced and, as a consequence, the Joule effect and the reversible heat effect are reduced, too. The now approximately constant gas evolution causes a corresponding heat generation.
- During the equalizing step, gas evolution (mainly required for mixing of the electrolyte, see Section 7.1.1.7) dominates. On account of the large difference between the actual charging voltage and the calorific voltage of water decomposition, heat generation is considerable, although the current is rather small.
- During discharge, heat generation is also small, owing to the small overvoltage, and further reduced by the reversible heat effect that now means cooling.

Heat Capacity. The temperature response of a battery to heat generation or heat loss is determined by its heat capacity according to Equa-

Table 14. Typical values for the heat capacity of various lead – acid batteries, and the share caused by the electrolyte

Type of battery	Heat capacity		Percentage caused by the
	$kJ\,K^{-1}\,kg^{-1}$	kJ/(K · 100 Ah)	electrolyte
Starter (flooded SLI ∗∗)	0.94 – 1.2	30 – 37∗	75 – 85 %
Traction (600 Ah, tubular)	1.05	7	76 %
Stationary (600 Ah, past.)	1.15	8	82 %
Stationary (600 Ah, tubular)	1.18	10	80 %
Valve-regulated	0.75 – 1.0	6 – 8	64 – 75 %

∗ per 12 V battery. ∗∗ SLI = starting, lightning, and ignition (starter battery for motor cars).

tion (3.31). In Table 14 heat capacities of some lead – acid batteries are compiled.

Table 14 shows that the heat capacity does not vary too much for the different types and is close to $1\,kJ\,K^{-1}\,kg^{-1}$. For batteries of similar design, it is mainly determined by the acid percentage of the battery weight, due to the high heat capacity of water.

Maximum Heat Generation During Discharging. To estimate possible heating effects at extremely high-rate discharges or even short-circuits, a specific energy of 35 Wh/kg can be assumed that is typical for a starter battery. With the specific heat capacity of $1\,kJ\,kg^{-1}\,K^{-1}$ the temperature increase would be:

$$\Delta T = \frac{35 \cdot 3.6}{1} = 126\,K$$

if the whole energy content were converted into heat and heat dissipation were excluded (adiabatic heating). This, however, is a theoretical value. Actually only a small fraction of the energy content can be drawn at such a high rate, partly because of the slow diffusion processes, partly because lead sulfate, precipitated at the surface of the active material, forms a barrier that hinders further discharge, and the residual energy content can only be drawn at a low rate. For this reason, lead – acid batteries cannot be heated up to detrimental temperatures by their own discharge. Even when discharged by short-circuiting and heat cannot dissipate, a temperature increase of $< 30\,°C$ is to be expected.

This, however, does not mean that loads above specified limits may not cause damage. Internal connectors or terminals may be interrupted by melting and the sparks may ignite explosive gas mixtures in the head space of the battery.

Heat Problems During Charging, Thermal Runaway. During charging, the energy that flows into the battery is limited by the charger that permanently supplies energy, different from the discharge of a battery that rather soon is exhausted due to its limited storage capability. Furthermore, when the battery is scheduled for a short bridging time, the charging device will be designed to supply a comparatively high current. If, for example, the standby battery is scheduled to bridge a current interruption of 10 min, the 10-minute rate will be the normal requirement of the concerned application and the charging device will supply the corresponding current. Thus, under unfavorable and uncontrolled conditions the battery might heavily be overcharged and a corresponding heat generation will result. In vented cells, the water loss can be so high that cells are dried out, and fire hazards might be the worst consequence. In valve-regulated lead – acid batteries (VRLA batteries), the intense heat generation of the internal oxygen cycle can cause a thermal runaway situation, where heat generation increases faster then heat can dissipate.

Such a situation can, however, only occur when the battery is not regularly controlled and short circuits in individual cells or failure of the charging device are not noticed (cf., e.g., [127]).

7.1.1.5. Valve-Regulated Lead – Acid Batteries

Valve-regulated lead – acid batteries (VRLA batteries) are based on the internal oxygen cycle, described in Section 7.1 but the unavoidable secondary reactions hydrogen evolution and grid corrosion disturb this cycle as indicated in Figure 61.

Figure 61. The internal oxygen cycle in valve-regulated lead – acid batteries that unavoidably is accompanied by evolution and escape of hydrogen, and by corrosion of the positive grid

As a consequence, the valve-regulated lead – acid battery cannot be made as a virtually sealed system. The evolved hydrogen has to leave the cell, since the rate of hydrogen oxidation that would form an internal hydrogen cycle is negligible. At the usual float voltage of about 2.25 V/cell, hydrogen evolution rates at minimum between 0.5 and 2 mL per 100 Ah and per hour are to be expected that escape periodically through the valve, if hydrogen is not lost otherwise, e.g., by permeation through the container wall.

Oxygen is consumed by corrosion. Both reactions mean water loss, although only to a very small extent that normally just causes a slight reduction of the performance data during service life. However, under unfavorable conditions (elevated temperature), water loss can be a serious aging factor, since it cannot be compensated by refilling.

Of great importance is that at a high efficiency of the internal oxygen cycle, hydrogen evolution must balance the corrosion rate to ensure proper float charging, as is described in detail in Section 7.1.1.7 and illustrated in Fig. 66.

The container of a VRLA battery must properly be welded, the terminals be sealed excellently, and the valve must close precisely. Otherwise oxygen, that permeates into the VRLA battery from the surroundings, quickly reaches the negative electrode and acts as an additional anodic current that causes discharge of the negative electrode.

The valve-regulated design has a number of advantages:

- Water loss is so widely reduced that refilling is not required for the whole service life.
- Hydrogen evolution is reduced to a fraction of that of vented batteries.
- Acid cannot be spilled, and acid fumes do not escape from the battery under normal operational conditions. For both reasons, the battery can be installed close to electrical equipment.
- VRLA batteries can be operated in horizontal positions which often saves volume required for the battery (cf. Fig. 72).

Due to their advantages, VRLA batteries came into widespread use within less than twenty years. In the field of stationary applications they substituted most of the vented batteries. However, they are more sensitive to unfavorable operational conditions than their vented sisters. They should always be carefully kept under control, especially when they are operated at elevated temperatures (cf., e.g., [128], [129]).

7.1.1.6. Discharge Performance

The discharge performance is largely determined by design parameters of the individual type of battery. Electrode thickness and size are such parameters, but also electrode spacing, kind of separation, and concentration of the electrolyte influence discharge performance.

A typical family of discharge curves is shown in Figure 62. The dotted line is the open-circuit voltage and represents the potential decrease caused by acid dilution (cf. Fig. 58). The slope of this curve is mainly determined by the electrolyte content in the cell.

As the load increases, the cell voltage does not only drop to a lower level due to the internal resistance, but also the actual capacity is reduced even at the lower end-of-discharge voltage. The reduction in capacity is caused mainly by decreased utilization of the active material at in-

creased current load. This again is a result of the rate-limiting diffusion steps.

The end-of-discharge voltage is determined by national or international standards.

Figure 62. Discharge performance of a traction battery with tubular plates, nominal capacity (5 h rate) 350 A h

Initial Voltage Drop. At the beginning of discharge of a completely charged lead – acid battery, a small minimum is observed in the voltage curve (coup de fouet in Fig. 5). This voltage drop, on the order of 20 – 30 mV, is interpreted as nucleation overvoltage, i.e., the completely charged surface of the positive plate does not contain sufficient $PbSO_4$ nuclei for further crystal growth and the precipitation of new crystals affords oversaturation [130].

The initial voltage drop is the reason that in discharge curves published by manufacturers (Fig. 62) the first 10 % of discharge time is omitted because this voltage drop depends on the pretreatment of the battery.

7.1.1.7. Charge Performance

The charge performance of the lead – acid battery depends largely on the limiting influence of kinetic parameters. The charge acceptance is high as long as the state-of-charge is low, but charge acceptance is reduced as the battery approaches full charge. When the battery is charged at constant voltage, this results in the typical current patterns shown in Figure 63.

As charging begins, charge acceptance is high, and the current is limited by the charger. When the charging process is nearly completed, the charging current approaches zero and the current is reduced to the oxygen/hydrogen-evolution rate (float current). Three parameters determine the charging process: the initial charging current, the charging voltage, and the charging time. Increased charging voltage is effective only as long as charge acceptance is high; towards the end-of-charge it only increases the rate of water decomposition. For this reason, charging at increased voltage is recommended only for a limited charging period. The most effective way to reduce the charging time is to increase the initial charging current (Fig. 63).

Figure 63. Charge acceptance at 2.25 V/cell; effect of initial charge current

Figure 64 shows the characteristic charging pattern for positive and negative electrodes, and for the cell. At the negative electrode, charge acceptance is close to 100 % for most of the charging time, as indicated by the horizontal curve III. The sudden switch to the hydrogen evolution potential corresponds to the cell-voltage step towards the end of the charge. The voltage curve of the positive electrode (curve II in Fig. 64) shows a slight increase from the beginning of the charging process, indicating a corresponding increase of oxygen evolution. This means that during the first stages of the charging process, the efficiency of the positive electrode is lower than that of the negative one. Because of different efficiencies, the positive plate is not charged completely when the voltage of the negative electrode suddenly increases, indicating complete charge of this electrode.

Actual charging schedules are always a combination of constant voltage and constant current steps as shown in Figure 60. When the battery is operated in charging – discharging cycles, a certain overcharge is required at the end of the cycle ("equalizing" in Fig. 60).

In flooded batteries, this final overcharge is mainly required to avoid acid stratification. During discharge, SO_4^{2-} is consumed at both electrodes. The resulting dilution of the acid means

reduction of its specific weight, and causes natural convection that mixes the electrolyte between, beside, and above the electrodes. Only the acid below the electrodes remains unchanged. During charging, the acid concentration is increased between the electrodes. Now the gravity causes mixing with the exception of the acid above the plates. At the end of the cycle, the acid above the plates is still diluted, while the concentration of the rest is slightly increased compared to the situation of a completely uniform concentration. If such cycles are repeated, a significant stratification of the acid is soon observed.

Figure 64. Constant current charging of a laboratory cell with excess electrolyte

To avoid stratification, conventional lead – acid batteries in traction applications are overcharged by 10 to 20 % per cycle to produce gas bubbles for mixing the electrolyte (the equalizing step in Fig. 60). This method is, however, not very effective and causes not only increased water loss, but also increased corrosion attack and heat generation, besides the fact that energy is wasted.

A superior method is to mix the acid by air-lift pumps (cf. [127, p. 258]). In such pumps gas bubbles are generated in a vertical tube by feeding a small volume of air from a central supply. These bubbles reduce the specific weight of the liquid inside the tube, which results in an upward movement of the acid column within the tube, and so acid is lifted from the bottom and poured above the top of the plates. Thus, complete mixing of the electrolyte can be achieved with a small amount of air and within a short period of time. Overcharging of traction batteries can so be reduced to about 4 % instead of 20 %. This method has been common for many years in submarine batteries [131] and is also used for solar applications. Since the beginning of the 1990s, it has been adopted for specially designed batteries for load-leveling applications [132] for electric vehicles [133], and also for normal traction applications [134].

In valve-regulated lead – acid batteries, acid stratification is no problem with gelled electrolyte due to the strong immobilization of the electrolyte. In cells with glass mat separators (AGM), a small influence of gravity is still observed, and the general recommendation is to avoid a separator height above about 30 cm by operating taller cells in a horizontal position (cf. Section 7.1.1.10). But VRLA batteries also require equalization charges when cycled. Here the reason is that the internal oxygen cycle consumes most of the current when the battery approaches the state of full charge. Small variations in the efficiency of this cycle would cause corresponding variations in the state of charge of individual cells within a string already after a fairly small number of cycles. For this reason, equalizing steps at increased voltage are usually applied in the charging schedule of VRLA batteries when cycled, although they increase the water loss to a certain extent (cf. [127, p. 422]).

Fast recharge is often desired, especially in electric vehicle applications. This can be achieved by high initial currents. In addition, such a high charging current is beneficial for the cycle stability of the active material, as more recent experiments with electric vehicles showed. However, controlled charging methods are a premise to avoid high-rate overcharging of individual cells in the battery.

Float Charging. One advantage of lead – acid batteries is that they can be recharged and kept fully charged at a voltage slightly above the equilibrium value. This is applied in many stationary applications where the battery is used as a standby battery and is only discharged for emergency energy supply if the network fails. Usually, the permanent overcharge, the float charge, is accomplished by connecting the bat-

tery to the d.c. power supply bus. Then the battery is continuously slightly overcharged, and in the case of a mains failure security is provided for uninterrupted power supply (although at a slightly reduced voltage).

Quasi float charging is applied to automotive batteries. Here the battery is also directly connected to the d.c. bus bar of the car, and is charged at a slightly increased voltage as long as the car runs (cf., e.g., [135]). But this charge is limited to the driving periods of the car, most of the time the battery stands at open circuit. It depends on the balance between charging periods and energy consumption, whether the battery really reaches the float situation. In many private cars, especially in winter time, the battery is not fully charged but remains between 75 and 90 % of its full charge.

Polarization of the positive and negative electrodes is an important parameter for float charging, since the positive electrode only remains fully charged when its potential is kept above its equilibrium value, while the potential of the negative electrode must be kept below its equilibrium value. At a given float voltage, polarization of the electrodes is determined by the general rule:

> Equal currents must flow through positive and negative electrodes

Figure 65 illustrates the situation for a flooded battery on float charge or overcharging at 2.25 and 2.35 V/cell, respectively. It corresponds in principle to Figure 59, but is drawn on a semilogarithmic scale and the value of the various parameters are quantified. The horizontal axis shows the electrode potential versus the polarization of the concerned electrode. The $PbSO_4/PbO_2$ and the $Pb/PbSO_4$ equilibrium potential in Figure 65 correspond to a definite acid density. Since negative logarithms do not exist, cathodic currents, like those for hydrogen evolution and oxygen reduction, are also drawn in positive direction.

In Figure 65, hydrogen and oxygen evolution form Tafel lines that are drawn with their typical slopes of 0.12 and 0.08 V per decade of current, respectively. These slopes and the vertical position of the Tafel lines depend of course on the individual parameters of the considered type of battery, such as cell design, used materials, and manufacturing methods. The values used in Figure 65 represent data that are typical for modern batteries with antimony free grid alloys (low hydrogen evolution). Increased hydrogen evolution, e.g., due to contamination by nickel or antimony, would cause a marked shift of the concerned curve in parallel to higher current values.

Corrosion is approximated by two Tafel lines, a falling one at small polarization values and an increasing one at higher polarization, which form a minimum at 60 mV above the $PbSO_4/PbO_2$ equilibrium potential. This is, of course, an arbitrary approximation, but reflects the general experience fairly well.

For oxygen reduction a limiting current density of 2 mA/100 Ah is assumed which applies for flooded batteries [136], where most of the generated oxygen escapes by ascending gas bubbles from the cell, and only a small portion reaches the negative electrode. At very low cell voltages, the generation of oxygen at the positive electrode can be the limiting factor as indicated by "lack of oxygen supply".

The rule that equal currents must flow though both electrodes is only fulfilled at a certain polarization of the positive and negative electrodes as indicated by the horizontal arrows. The broken curves in Figure 65 represent the total current

- hydrogen evolution + oxygen reduction at the negative electrode
- oxygen evolution + grid corrosion at the positive electrode.

In this example, at 2.25 V/cell a float current of 13 mA/100 Ah results. At the negative electrode, hydrogen evolution and oxygen reduction contribute 11 mA and 2 mA, respectively, while at the positive electrode it is the sum of 2.4 mA by corrosion and 10.6 mA by oxygen evolution. With the data used in this example, the result is a critically low polarization of the positive electrode due to the low hydrogen evolution rate that requires a comparatively large polarization of the negative electrode. Such a situation usually is experienced, when low float voltages are applied to flooded antimony free batteries, and it is a well known practice to preserve full capacity of the positive electrode by addition of traces of platinum that depolarize the negative electrode (increase the hydrogen evolution rate) [137].

Hydrogen evolution equals hydrogen escape, since hydrogen oxidation at the positive elec-

Figure 65. Float charging and overcharging of a flooded lead – acid battery

trode can be neglected. In this example, hydrogen evolution corresponds to an equivalent of 11 mA.

The total loss of oxygen is also equivalent to 11 mA: an equivalent of 8.6 mA escapes, an equivalent to 2.4 mA is lost by corrosion, while an equivalent of 2 mA is recombined at the negative electrode and so remains within the cell.

Summed up for a year's period, these figures mean a coulomb equivalent of 96 Ah (11 mA × 24 h × 365/1000) which corresponds to a water loss of 32 g per year and 100 Ah (1 Ah decomposes 0.336 g water).

Water loss is proportional to hydrogen escape. Thus water loss can be derived from determination of the amount of gas evolved combined with gas analysis. Determination of the weight loss is misleading, since the oxygen lost by corrosion remains in the cell. This applies also for VRLA batteries.

When this battery is overcharged at 2.35 V/cell, the polarization of both electrodes is automatically increased to fulfill the above rule that equal currents flow through positive and negative electrodes. Water loss is then increased to an equivalent to 34 mA or 297 Ah per year, i.e., 100 g water is lost per year and 100 Ah. This is an increase by approximately a factor of 3 compared to the voltage of 2.25 V/cell.

Figure 66 illustrates the situation for the valve-regulated design of the same battery, under the assumption that the efficiency of the internal oxygen cycle is 100 %, i.e., all the oxygen, that is generated at the positive electrode, is subsequently reduced at the negative electrode. (In practice, values very close to 100 % are usually reached). Since oxygen evolution is completely compensated by oxygen reduction, the equivalents of hydrogen evolution and corrosion must equal each other. Otherwise, the fundamental rule would be violated that equal currents have to flow through both electrodes. Consequently, polarization of both electrodes is now determined by the balance between hydrogen evolution and grid corrosion, as indicated by the broken horizontal double arrows.

At the float voltage of 2.25 V/cell, the required balance is reached at a polarization $\eta_- = -11$ mV and $\eta_+ = 99$ mV of negative and positive electrodes, respectively, and the resulting float current is 106 mA/100 Ah (103 mA O_2 evolution + 2.6 mA corrosion at the positive electrode and 103 mA H_2 evolution + 2.6 mA O_2 reduction at the negative electrode).

Compared to Figure 65, the situation in Figure 66 is quite different, although both are based on the same cell data. In the vented design (Fig. 65), the polarization of the electrodes is mainly determined by the balance between hydrogen and oxygen evolution. In the valve-regulated design, the polarization of the electrodes depends on the balance between hydro-

Figure 66. Float charging of a valve-regulated battery, under the assumption that the internal oxygen cycle has an efficiency of 100 %

gen evolution and grid corrosion, although both reactions contribute only to a small portion of the current.

Figure 66 indicates the typical situation in the VRLA battery: The polarization of the negative electrode is small compared to that of the positive one. The advantage of this situation is the correspondingly reduced hydrogen evolution. Only an amount equivalent to 2.6 mA is evolved, i.e., only 24 % compared to the vented design in Figure 65, although the float current is much higher. Water loss is correspondingly reduced. Oxygen is not lost from the cell. Only an oxygen equivalent of 2.6 mA is consumed by corrosion. 2.6 mA correspond to 23 Ah per year, that is equivalent to 8 g of water. The initial water content of a VRLA battery is about 1000 g per 100 Ah. So, in this example 0.8 % of the water content would be lost per year.

Figure 66 however, also shows a problem that may be encountered with valve-regulated batteries: If in this example, hydrogen evolution would slightly be increased, or the cell voltage be decreased, the required balance to corrosion could only be achieved at a positive polarization of the negative electrode, but this means discharge. Under such conditions, after a certain period of float charging, the full capacity of the battery could no longer be drawn, due to partly discharged negative electrodes, although the battery had properly been floated at the specified voltage.

At a higher charging voltage, as shown by "overcharging at 2.35 V/cell", the situation at the negative electrode is less critical, since the positive electrode is polarized to values with an increased corrosion rate. The so increased deficit between float current and oxygen evolution requires a correspondingly increased hydrogen evolution. This again causes a more negative polarization of the negative electrode, and ensures so that it remains fully charged. In practice, however, float charging at an increased voltage is usually not possible. But terminated boost charging or equalizing charging is occasionally included in monitoring routines for valve-regulated lead – acid batteries to recoup the full capacity of the negative electrodes [138].

As a consequence, the manufacturer of valve-regulated lead – acid batteries has to consider the balance between hydrogen evolution and grid corrosion. If highly corrosion resistant alloys are applied for the positive grid, a corresponding low gassing rate of the negative electrodes is required. The use of highly purified lead for the active material in the negative electrode would be the consequence. Battery practice, however, shows, that the required balance not always can

be reached and that "discharged negatives" occasionally are observed.

Developments during the 1990s indicate that the application of a small catalyst within the cell can be used as a remedy against such an imbalance caused by a too high hydrogen-evolution rate [139–141]. The catalyst in the top space of the cell recombines a certain portion of the oxygen directly with the abundant hydrogen, reduces so the efficiency of the internal oxygen cycle and in this way effects the required polarization of the negative electrode. Water loss is not increased, since the gas that is recombined by the action of the catalyst remains as water within the cell and water loss is even slightly reduced to the equivalent of corrosion.

7.1.1.8. Technical Design and Manufacturing

Batteries are mostly designed for specific applications. This leads to an indeterminable number of different designs. Only a few of the most important features can briefly be treated in this article.

Plate Construction, Cell Design. The design of the electrode must provide both mechanical support for the active material and electronic conductivity for the collected current. The most common plate design is the *grid plate* or pasted plate. A network of lead wires is filled with pellets of active material. The grid itself may be produced by casting of lead or lead alloys or by expanding or punching sheet metal. Two examples of grids are shown in Figure 67.

Figure 67. Two examples of SLI-battery grids with ohmic resistance map [142]
A) Cast grid; B) Expanded lead strip

The basic material for positive and negative active material usually is gray oxide, a fine powder consisting of about 70 – 80 % lead oxide (PbO) and the rest lead. This powder is mixed with water and sulfuric acid to form a paste, which is applied to the grid by pasting machines. To improve the mechanical strength of the active material, short fibers (0.1 – 0.2 %) are added. Furthermore, the paste applied in the negative electrode contains expanders, e.g., organic substances and barium sulfate, which maintain the activity (surface area) of the negative electrode material.

After the plates are pasted they are dried gradually over several days under controlled conditions. During this *curing process* 95 – 98 % of the lead in the paste is oxidized and the water, which originally accounts for 50 vol % of the paste, is evaporated. The volume occupied by the water forms the pore volume of the active material.

In most cell designs several plates are connected in parallel to form a plate group (Fig. 68). The positive (b) and negative (a) plates face each other. Separators between plates of different polarity prevent short circuits. The metallic extensions of the grids, called lugs (c), are welded to a top bar or strap (d) and the terminal post (e).

Figure 68. Pasted or flat plate group, without separators
a) Negative plate; b) Positive plate; c) Lug; d) Connecting bar; e) Terminal post

Often, a number of cells are combined into a common container to save volume and weight and form a mechanically stable unit. Such *block batteries* or monoblocks are mainly used with three cells (6 V block) or six cells (12 V block).

The usual starting, lighting, and ignition (SLI) battery in the motor car is a 12 V block.

Block batteries, as in Figure 69, are used in all kinds of electric vehicles like passenger cars, but also battery-powered handcarts. A further field of application is in wheel-chairs, where VRLA batteries are preferred due to the fact that acid cannot be spilled. Furthermore, the cycle performance of such valve-regulated batteries is superior to corresponding batteries of the flooded design [143] [$>$ 700 cycles (80 % depth of discharge) compared to $>$ 400 for similar batteries of vented design]. The main reasons for this superiority are that acid stratification does not occur and shedding of active material is prevented.

Figure 69. Valve-regulated lead – acid battery with gelled electrolyte for traction; three cells (6 volt), 160 Ah (Sonnenschein)
1) Valve (opening pressure $\approx$ 10 kPa); 2) Positive terminal; 3) Cell cover (polypropylene); 4) Intercell connection; 5) Pole bridge; 6) Container (polypropylene); 7) Positive plate; 8) Microporous separator with glass felt adjacent to the positive electrode (not a microporous glass mat); 9) Negative Plate

A different design principle is shown in Figure 70. It is used for batteries in the capacity range between 2.5 and 25 Ah. On the left, a cross-section of a monocell battery, on the right a 12 volt-block composed of six of these cells are shown. Each cell contains one positive and one negative electrode, which are separated by an absorbent-glass mat and spirally wound to form the cell element. The grid is punched from a lead sheet (no alloying additives, except a little amount of tin), soft enough to be wound as shown in the cutaway cell of the block battery. The cross-section shows how the grid is surrounded by the active material.

The cell is sealed in a polypropylene container, welded to a cover of the same material. In the monocell the container is mechanically supported by a metallic casing. A number of lugs on the top edge of the electrodes are welded to the terminal. The valve consists of a synthetic rubber cap which in the monocell opens at 3 to 4×10^5 Pa and in the blockbattery between 4.1×10^4 and 5.5×10^4 Pa because of the reduced mechanical support of the cells compared to the monocell. (In most VRLA batteries, the opening pressures are in the range of 10 kPa to prevent bulging of the container. Since such batteries are not overcharged at high current rates, the partial pressure of oxygen in the gaseous phase remains so low that it cannot open the valve, and that only insignificant amounts of oxygen escape when hydrogen exceeds the opening pressure of the valve).

A battery also based on wound electrodes, but designed for extremely high loads uses thin foils (0.05 mm) of a lead tin alloy instead of grids. The active material is coated on both sides in 0.075 mm layers. The separator (absorbent-glass mat) is 0.18 mm thick) [146].

The *tubular plate* design, sometimes called ironclad plate, is common in many countries for the positive electrode (Fig. 71). The principle of this design is to separate the conducting elements from the components which contribute mechanical support. The grid consists of vertical lead rods, which are the centers of tubes formed by woven, braided, or nonwoven fabrics. The tubes are filled with gray oxide or minium powder; some manufacturers use a paste-filling process. Improved utilization of the active material is the advantage of the tubular electrode. The central current collecting spine produces homogeneous current flow across the active material, and the mechanical support by the tube allows use of rather light, active material, which is equivalent to high porosity.

Figure 70. Battery with spirally wound electrodes (Left: Monocell [145]; right: 12-volt block)
1) Valve; 2) Grid, punched from lead; 3) Positive and negative electrodes; 4) Glass-mat separator; 5) Polypropylene container (as a monocell encased by a metallic housing); 6) Terminal (bobbin contacts or thread (for 25 Ah only); 7) Monoblock cover; 8) Intercell connector; 9) Spirally wound element of the two electrodes and the separator

Figure 71. Tubular plate cross section
a) Lead alloy spine; b) Active material, PbO_2; c) Tube, in this example mixed fabric of glass and polyester fibers; d) Bottom seal of plastic caps

Tubular plates are in widespread use for flooded traction and stationary batteries. But they are also applied for VRLA batteries (see Fig. 72).

Figure 72. Stationary valve-regulated lead – acid battery with gelled electrolyte (Sonnenschein dryfit A 600)
48 volts, 1000 Ah (2 strings in parallel)

Figure 72 clearly demonstrates an advantage of valve-regulated lead – acid batteries, namely

that the blocks or cells can be operated in horizontal position. Despite the compact installation, easy access is given to each terminal for voltage measurements. But attention has to be paid to the high weight of lead – acid batteries. It may exceed the load capacity of the floor. Furthermore, heat problems may arise if the current flow is too high to be compensated by the cooling effects. A spacing of at least 1 cm has to be provided around each block or cell if heat dissipation by air convection is to be effective.

The *Planté plate* is an old plate design, based on castings of pure lead.

Figure 73 is a cross section of a Planté plate common in Europe. The lamellas of the casting enlarge the surface area by a factor of 8 – 12. The layer of active material is thin (ca. 200 μm). It is produced by anodic corrosion using perchloric acid to increase the corrosion rate. The thin layer of active material in combination with the large surface area of the current collecting lead body results in an excellent high-rate performance. The corrosion resistance of pure lead guarantees long service life. Disadvantages of Planté plates are the poor relation of capacity – lead content, and a poor capability for charge – discharge cycles because of capacity loss.

Figure 73. Planté plate cross section

Planté plates are still in use for flooded stationary batteries. Like tubular plates, they are always combined with negative grid plates.

In a battery especially designed by Bell for telephone stations, saucer formed pastes plates form horizontal stacked electrodes [147].

Formation, "Dry" Delivered Batteries. The conversion of lead oxide or minium to the final active material, i.e., lead and lead dioxide, is achieved by an electrochemical process called formation. *Tank formation* is formation of the plates before they are installed in the battery container. Usually positive and negative plates are assembled together in special jars with excess acid and, when the current flows, the material in the positive electrode is converted to lead dioxide, while that in the negative electrode is reduced to lead. After this process the plates are washed and dried. The spongy lead of the negative plate can be preserved by special treatments, otherwise the moist plate would react violently with oxygen to re-form lead oxide. A tedious recharge process would be required to recover full capacity. Charge preserving processes are: drying in vacuum, in vapor, or in hot mineral oil, or immersion in boric acid solution prior to the drying stage. Preserved negative plates can be stored for years without a significant loss of capacity. Cells equipped with precharged dry plates can be filled and put into service without any recharge even after long storage time. The service life starts with filling.

The lead dioxide in the positive electrode does not need preservation; the only requirement is to remove the sulfuric acid by thorough washing; otherwise the plate could not be dried.

Often raw plates are assembled in plate groups and inserted into the cell container prior to "jar formation," "cell formation," or "battery formation." The advantage of jar formation is that washing and drying after formation is avoided. On the other hand, these batteries can only be delivered filled with electrolyte, which has the consequence of limited storage time.

Valve-regulated lead – acid batteries are always delivered in the filled state.

7.1.1.9. Lead Alloys

The unavoidable corrosion of the positive grid and other parts of the conducting material has far-reaching consequences for the lead – acid battery:

1) Grid corrosion finally limits service life of every lead – acid battery, unless other failures occur earlier. A battery designed for a long service life must be equipped with a corresponding "corrosion reserve" of the positive grid.
2) Grid corrosion is a water consuming reaction which is of great importance in valve-regulated lead – acid batteries.

Table 15. Grid alloys for lead – acid batteries, their characteristic additives and fields of application

Kind of alloy	Additives	Field of applications
Standard antimony	4 – 11 % Sb, As, Sn, Cu (Ag)	traction
Low antimony	0.5 – 3.5 % Sb, Se, Te, S, Cu[a], As, Sn (Ag)	low maintenance (stationary, traction) SLI batteries
Standard calcium	0.06 – 0.12 % Ca, 0 – 3 % Sn, (Al)	stationary, vented and VRLA batteries SLI batteries
Low calcium	0.02 – 0.05 % Ca, 0.3 – 3 % Sn; Ag 0.008 – 0.012 % Al	valve-regulated, SLI batteries (continuous grid manufacturing)
Lead – tin	0.2 – 2 % Sn	valve-regulated batteries, conducting elements
Pure lead		Planté plates, Bell System round cell, (Bell Linage 2000)
ASTAG, ASTATIN[b]	0.009 % As, 0.065 Te, 0.08 % Ag (+ Sn = ASTATIN)	submarine batteries stationary batteries (Scandinavia, Italy)
Antimony – cadmium[c]	1.5 % Sb, 1 % Cd	valve-regulated

[a] Se, Te, S, and Cu are added as "grain refiners". [b] Alloys used by the Tudor Group in Scandinavia. [c] Only used by GNB.

The selection of appropriate alloying additives is of immense importance, since the rate of grid corrosion is influenced by the composition of the grid alloy. Furthermore, alloying constituents are released when the grid material is transformed into lead dioxide. These substances can be leached out of the positive plate and reach the negative electrode by diffusion, and cause increased hydrogen evolution by contamination (cf. Section 7.1.1.2).

Thus, the selection of grid alloys must not only consider fabrication requirements (to produce flawless grids), mechanical strength (for handling during production), creep strength (to resist growth during service), and corrosion resistance, but also pay attention to the fact that the alloy and the alloying constituents may cause electrochemical problems. As it is not possible to fulfill all these requirements at their optimum simultaneously, a number of different grid alloys are in use. They are described in detail in → Lead Alloys. (A survey on metallurgical properties of lead alloys for batteries is also given in [148]).

Table 15 shows the most frequently used alloy and their field of application.

7.1.1.10. Separators

In lead – acid batteries, the separator must not only prevent direct contact between the electrodes, but it also has to provide space for the required volume of acid. This is achieved by ribs or additional spacers or glass mats. Furthermore, the separator must suppress the growth of lead dendrites from the negative to the positive electrode.

PVC, rubber, polyethylene, and phenolic resin supported by polyester fibers are the most frequently used basic materials for separators in flooded batteries. An inexpensive separator that has been mainly used in SLI batteries is based on cellulose soaked up in phenolic resin that protects the cellulose fibers. Nowadays it is widely substituted by polyethylene and PVC based separators.

Sintered PVC separators are easy to manufacture. Their pore system is formed by voids between the sintered particles. Disadvantages are that they contain a certain amount of larger pores and that a certain thickness is required for their mechanical stability. For another kind of PVC separators, the molten plastic is extruded together with a high portion of silica (SiO_2) that forms the rather uniform and fine pore system (≈ 0.1 µm). Rather uniform pores of about 1 µm can also be obtained by addition of starch that later is extracted [149].

Polyethylene separators also contain silica, but also oil that later is extracted. In the *phenolic resin – polyester* separator a rather uniform sys-

tem of fine pores (1 μm) is formed by a special curing process of the resin.

Rubber separators are the oldest types. They also contain silica but also expanding additives to form the pore system. Rubber separators are still used in larger types of industrial batteries.

In many applications, mainly in SLI batteries, separators are used as pockets that envelope the plates and prevent dendritic growth of lead around the edges. In this regard, it is an advantage of PVC and polyethylene that both can easily be heat sealed.

AGM separators that are used in VRLA batteries, simultaneously act as the separator and the spacer that contains the electrolyte (cf. Section 7.1.1.5). Since glass is wetted by sulfuric acid, the glass fibers are covered with liquid and so the small voids between them are filled with electrolyte. Larger voids are not filled and form the pores for gas transport. To achieve the desired ratio of filled and open pores, glass fibers of different diameter are mixed. Sometimes, layers of different fiber types are combined to achieve uniform gas transport across the separator [149]. When the cell is assembled, a certain compression of the glass mat has to be observed. Otherwise, the contact between the separator and the electrode surface might be lost and cause capacity decay after a certain service life, since water loss causes a slight shrinkage of the glass mat.

Batteries with jellified electrolyte require conventional separators between the positive and negative electrodes, since the gel itself would allow the penetration of lead dendrites. Due to this additional separator, the internal resistance of a gel battery is slightly higher than that of a corresponding type with AGM separation. On the other hand, the influence of gravity is smaller in batteries with gelled electrolyte. Gelled sulfuric acid behaves in the same way as in a felt with a pore structure one order of magnitude finer than that of the usual microglass-mat separator. So the acid is more strongly fixed and gravity effects that are observed in a 30 cm high AGM battery would be observed to a similar extent in a 3 m high battery with gelled electrolyte. As a consequence, tall cells with gelled electrolyte can be used upright, while for corresponding AGM batteries the operation in horizontal position is mostly recommended to avoid stratification effects. For the same reason, the gel prevents electrolyte stratification even during extensive cycle operations.

7.1.1.11. Container Material, Post Seals

Containers nowadays are nearly exclusively made of plastics; seldom is hard rubber used. Because of its high impact resistance, relatively soft polypropylene is preferred for starter batteries or for small block batteries which attain mechanical strength by the multicell structure. It is also the material of choice for vehicle power batteries where the cell containers are supported by a tray (cf. Fig. 77).

Stiffer materials, such as polystyrene, or copolymers, like (styrene–acrylonitrile, SAN, shock-resistant polystyrene), are preferred for stationary batteries where the single cells usually are installed without any support (cf. Fig. 74). In special cases polycarbonate (extremely shock-resistant) or PVC (flame-resistant) is used.

Figure 74. Portion of a large, stationary battery

In most cases the lids are heat-sealed to the container; adhesive is only used for big stationary batteries. The post seal to the container cover or to the container itself is an important construction detail. Sulfuric acid wets the lead post, creeps along the surface, and tends to penetrate the seal. At the positive post this penetration may be accelerated by corrosion (Pb oxidizing to PbO_2), which, under unfavorable conditions, may result in detrimental crevice corrosion. Many battery manufacturers have made efforts to achieve post seals which definitely prevent acid leakage in order to achieve the maximum service life of the battery.

Figure 75. Post seal for stationary batteries (courtesy of Varta)
a) Injection-molded plastic sleeve; b) Grooves; c) Copper or brass insert to improve conductivity and contact to connector; d) Cable connector; e) Plastic cover; f) Bolt; g) Seal sleeve and cover; h) Cell cover; i) Lead post

Figure 75 is an example of a post seal. Grooves (b) are cut in the post and covered by an injection-molded sleeve (a). The shrinkage of this sleeve forms a tight seal around the lead post. Even after several years of service the acid penetration usually does not occur beyond the second groove.

In VRLA batteries, corrosion problems of the terminal post are of minor importance, since the distance between the electrolyte level and the post is larger, and acid fumes are hardly present. Nevertheless the post seal has to be made carefully, since any leakage would allow the penetration of oxygen into the cell and cause self-discharge of the negative electrode.

7.1.1.12. Vents, Valves

In *flooded lead–acid batteries*, the vent plug permits the exchange of gas between the interior of the cell and the surrounding atmosphere. Normal vent plugs have only a few narrow holes to keep the evaporation rate of water low. Furthermore, vent plugs are frequently fitted with porous disks or cylinders that only allow the passage of gas or vapor and retain fumes. Simultaneously, these disks prevent ignition sparks or flames from entering the cell from the outside.

In *VRLA batteries*, the valve allows only escape of gas from the cell to avoid overpressure that leads to deformation of the container (bulging of the cell) and may cause problems in regard to the contact pressure within the plate block. The valve must, however, totally prevent any flux or diffusion of air into the cell. If air penetrates, the atmospheric oxygen content of 21 vol % is reduced at the negative electrode and causes chemical self-discharge.

Two valves that have been developed for mass production under the aspect of high reliability are shown in Figure 76. Their parts have to be made with high precision.

Figure 76. Valves for batteries, based on the deformation of elastomers
a) Both valves are made up of only three parts; b) Elastic cap in (A) or base of EPDM or FPM in (B); c) Outlet; d) Enlarged area for pressure response; e) Dynamic seal; f) Casing; g) Permanent seal (large area in (A) or sealing bead in (B)) [150]

The valve in Figure 76 A corresponds to a Bunsen valve. Such a valve is based on a rubber ring or cap that closes the opening of the cell in normal conditions, but is blown open when the internal pressure exceeds a specific limit. This design is widely used in small VRLA batteries. In the example of Figure 76 B, a cup of an elastomer forms the seal. Three grooves in the cap enlarge the surface area and so enhance the pressure response (the cut through one is shown in

the Figure). Furthermore, the seal is reduced in this section to a small edge (in Fig. 76) while the nongrooved section of the cap provides a safe permanent seal of a correspondingly large area (in Fig. 76) between the casing and the cap. This small edge is beneficial to achieve a definite opening pressure, since it reduces the danger that the cap sticks to the plastic tube.

The elastic base in Figure 76 B forms a butterfly valve. A bead seals the rest of this base so that air intake is absolutely prevented.

Oil can be used to improve the situation in both valves. Furthermore, both can be placed into a vent cup or into the lid of the container. Often such valves are covered by a sintered disk to prevent ignition from outside.

7.1.1.13. Water Refilling Systems, Forced Acid Agitation

Automatic water refilling systems are used for traction batteries.

In Figure 77, for example, each cell is equipped with a valve plug which automatically cuts water inflow when a float is lifted by the electrolyte level.

Figure 77. Traction battery (24 V, 500 Ah) equipped with automatic water refilling system (Varta Aquamatic)

The water pipe is simultaneously connected to its supply when the battery is connected to the charging device, but, water supply starts only at the end of the charging process to prevent overfilling.

7.1.1.14. Catalytic Gas Recombination

In flooded batteries, catalytic recombination of hydrogen and oxygen, with the produced water returning to the cell, is one alternative to reduce water loss. Appropriate devices are on the market and are installed instead of the usual vent caps [151]. These devices contain traces of palladium as the catalyst. Catalytic efficiency reaches 90 % or more, but some of the produced water is lost as water vapor. The efficiency (referred to water loss) therefore is reduced about 60 – 80 %. Nevertheless, recombination devices can extend the maintenance interval by a factor of three to five.

The possibility to improve the float charge behavior of VRLA batteries by catalysts has been described at the end of Section 7.1.1.7.

7.1.2. Batteries with Alkaline Electrolyte

A number of secondary battery systems is based on alkaline electrolyte, nearly almost diluted potassium hydroxide (KOH), because of its higher conductivity compared to that of sodium hydroxide (NaOH). Technically most important are nickel – cadmium and nickel – metal hydride batteries, especially as small sealed power sources for portable applications. Nickel – hydride batteries are employed as storage batteries in most satellites, for terristic applications they are too expensive. Nickel – iron batteries cannot be sealed because of the unavoidable hydrogen evolution at the iron electrode. They were mainly used as inexpensive traction batteries, but gradually lost their market share. The nickel – zinc system is attractive because of its high storage capability and its inexpensive negative electrode material. Despite enormous efforts that contiguously have been spent, however, an acceptable solution has not yet been found, because of the problems to recharge the zinc electrode. The silver oxide – zinc system is the most powerful alkaline storage system. Its high price and the limited number of possible recharges, however, limits use to special applications.

7.1.2.1. Nickel – Cadmium Batteries

The nickel – cadmium battery is one example of a larger number of batteries, based on an alkaline electrolyte (cf. rows 2 to 8 in Table 13).

Nickel – cadmium batteries have been in industrial production nearly as long as lead – acid batteries. In their sealed version they have gained enormous technical importance as maintenance-free batteries.

Characteristic features of nickel – cadmium batteries are:

- The electrolyte is (almost) not involved in the cell reaction, its concentration changes during charging or discharging can be neglected, and its volume can be minimized, which results in a battery of low weight and low internal resistance. Furthermore, the conductivity of the electrolyte remains fairly constant.
  As further consequences, problems of electrolyte stratification (see Section 7.1.1.7) are of little significance, and the fairly constant electrolyte concentration means a constant low freezing point of the electrolyte (between – 30 and – 60 °C).
  These features are the reason for the excellent high-rate and low-temperature performance of nickel – cadmium batteries and their capability of intermediate charging.
- Corrosion reactions of the current-conducting parts can usually be neglected during normal operation. A certain exception are foam electrodes (see Section 7.1.2.1.8), but even there the corrosion problem is not comparable with that in lead – acid batteries.
- Hydrogen is not evolved at the equilibrium potential of the cadmium electrode. Thus, hydrogen evolution can be avoided under certain preconditions (oversizing the capacity of the negative electrode so that always a rest is left uncharged as "charge reserve" and avoidance of too high charging currents).
  Since neither hydrogen evolution nor corrosion occur, nickel – cadmium batteries can be sealed completely, and the only reaction during overcharging is the internal oxygen cycle, described in Section 7.1. Such batteries are absolutely independent of their operational position, electrolyte cannot be spilled, and gases or fumes do not escape from the battery. For all these reasons, sealed nickel – cadmium batteries are ideal for the cordless power supply of electric or electronic devices and are in widespread use.

7.1.2.1.1. Thermodynamic Situation

Figure 78 illustrates the general situation for nickel – cadmium batteries. The sketch corresponds to Figure 59, but for the x-axis two scales are employed: The upper one represents the potential referred to the hydrogen electrode in the same solution (HESS). Since the equilibrium potentials of all the reactions in Figure 78 are shifted in the same manner with changing pH value (– 0.059 V/pH), this scale is independent of the electrolyte concentration.

The lower scale represents the electrode potential referred to the SHE. The electrolyte density has to be considered in this case, because, referred to this scale, all potentials in the Figure, are shifted with KOH concentration by – 0.059 V/pH.

The equilibrium potential of the cadmium electrode is 20 mV more positive than that of the hydrogen electrode. As a consequence self-discharge of the cadmium electrode caused by hydrogen evolution does not occur. Furthermore, *hydrogen evolution* can completely be avoided, if the (negative) polarization of this electrode during charging is kept so small that the hydrogen equilibrium potential is not reached. In practice, overcharging at the 5-hour rate is possible for many of the sealed designs without hydrogen evolution.

Oxygen evolution cannot be avoided at the positive electrode, because already the equilibrium potential of this electrode exceeds the equilibrium value of oxygen evolution.

Oxygen reduction occurs at the negative electrode. In flooded nickel – cadmium batteries this limiting current is as low as that in vented lead – acid batteries. In sealed nickel – cadmium batteries with immobilized electrolyte, oxygen transport rates can be quite high, and the internal oxygen cycle (cf. Fig. 61) can be correspondingly fast due to void volume within the separator and narrow spacing of the electrodes.

Corrosion of the nickel substrate in the positive electrode usually is negligible, and thus not shown in Figure 78.

7.1.2.1.2. Charge/Discharge Reactions

The discharge reaction (the oxidation) of the negative electrode is

Figure 78. Equilibrium potentials of the negative and positive electrodes in a nickel – cadmium battery and current – voltage curves of hydrogen evolution, oxygen evolution, and oxygen reduction. (The latter is limited by the oxygen transport rate, as indicated by the horizontal curve). The SHE scale corresponds to a KOH solution of 1.250 g/cm^3 or 26 wt % at 25 °C.

$$Cd + 2\,OH^- \longrightarrow Cd(OH)_2 + 2\,e^-$$

When the positive electrode is discharged, Ni^{3+} ions are reduced to Ni^{2+} according to the (simplified) equation

$$NiOOH + H_2O + e^- \longrightarrow Ni(OH)_2 + OH^-$$

When both are summed up, the cell reaction during discharge results, that can formally be written as:

$$2\,Ni(OOH) + 2\,H_2O + Cd \longrightarrow 2\,Ni(OH)_2 + Cd(OH)_2$$

For the positive electrode, the reactions in fact are more complicated. Nickel hydroxide is not a stoichiometric chemical compound, and not only trivalent nickel ions are present in the charged material, but it can be a mixture of Ni^{2+}, Ni^{3+}, and Ni^{4+} (cf. Fig. 79). The charged state should be written more precisely as $u\,NiO_2 \cdot v\,NiOOH \cdot w\,H_2O$, where u, v, and w are factors that describe the share of the three components [152].

Furthermore, the reactions at the nickel hydroxide electrode are not quite reversible. Thus, the positive electrode in nickel – cadmium batteries does not attain a true equilibrium potential, and thermodynamic data and values are only approximate.

While the discharging/charging reaction of the cadmium electrode occurs via the dissolved state, the nickel ions are charged and discharged in the crystal lattice; as illustrated in Figure 79. To preserve electrical neutrality, a corresponding number of protons must migrate into the crystal lattice during the reduction (the discharge) of the Ni^{3+} or Ni^{4+} ions. Otherwise, the increasing space charge within the crystal would soon stop the process. When the nickel electrode is charged (oxidized) as shown in Figure 79, these protons have to leave the crystal lattice. This exchange of protons is accompanied by the formation of a reduced or an oxidized crystallographic phase. Figure 79 shows the oxidation and reduction of nickel hydroxide in an idealized form.

Actually, the charging/discharging reactions are complex. Two different couples of charged/discharged species have been specified: the β/β couple and the α/γ couple which are not independent of each other [153]. Both couples are characterized by a different maximum oxidation

Figure 79. Charge and discharge of the nickel hydroxide electrode with simultaneous release and absorption of protons and incorporation of a small amount of potassium ions

state and different contents of KOH. The α/γ-couple absorbs about four times as much KOH as the β/β-couple [154]. Beyond that, the active material in actual battery electrodes shows poor crystallinity, and the reactions do not lead to definite chemical compounds, but cause progressively increased or decreased oxidation of the nickel ions (Ni^{2+}, Ni^{3+}, and Ni^{4+}). The consequence in battery practice is that the attained state of charge of a nickel hydroxide electrode depends on the charging period and on the electrode potential [155].

A remarkable feature of the above given simplified charge/discharge reaction is that neither KOH nor potassium appear in it or in one of the electrode reactions. Only H_2O and its dissociation product OH^- ions take part. Water, however, is the main constituent of the electrolyte, because the usually applied concentrations of KOH are in the range of 20 – 32 wt % (densities at 20 °C between 1.19 and 1.30 g/cm^3). From the discharge equation it can be deduced that 0.67 g water are required per Ah of discharge. Since in vented nickel – cadmium batteries, a minimum of 10 g of electrolyte is contained per Ah of nominal capacity, the change in density is only 0.015 g/cm^3, which will not be noticed in practice. In sealed batteries, despite their lower content of electrolyte, the density change caused by discharge does not exceed 0.02 g/cm^3, and can thus also be neglected.

7.1.2.1.3. Equilibrium or Open-Circuit Voltage

The free enthalpy of the discharge reaction is $\Delta G = -256$ kJ.

Inserting this value into Eq. (3.2) results in the equilibrium or open-circuit voltage: $U^o = 1.32$ V, in practice $U^o \approx 1.3$ V. Actually, after charging values between 1.3 and 1.4 V are observed, depending on the previous treatment of the battery. But on open circuit the cell voltage decreases to less than 1.3 V within about ten days [156].

The temperature coefficient of the equilibrium voltage is according to Equation (3.6)

$$\frac{dU^o}{dT} \approx -0.45\,\mathrm{mV/K}$$

This decrease of the equilibrium voltage of about 0.5 mV per kelvin can usually be neglected in battery practice.

7.1.2.1.4. Reversible Heat Effect, Calorific Voltage

The reversible heat effect of the discharge reaction is $Q_{rev} = T\Delta S \approx -26$ kJ per formula conversion of the cell reaction. Comparison with the value for ΔG shows that the reversible heat effect is 10.5 % of the converted energy when the nickel – cadmium battery is discharged or charged.

The negative sign means that additional heat is generated during discharge; and attention has to be paid to the heat balance when the battery is discharged with extremely high currents.

During the charging process, the reversible heat effect causes remarkable cooling as long as the heat generating secondary reaction of water decomposition does not occur. As a heat source, however, water decomposition can only be critical when the cell voltage considerably exceeds 1.48 V (= U_{cal} for water decomposition). As a result, vented nickel – cadmium batteries can be charged at quite high rates without suffering heat problems. But in the sealed version, the much higher heat generation by the internal oxygen cycle can cause serious thermal problems (see Fig. 81).

7.1.2.1.5. Heat Capacity (Specific Heat Content)

The temperature response of the battery to heat generation or heat loss is determined by the heat capacity of the battery, which can be calculated according to Equation (3.31). Table 16 gives characteristic heat capacities of some nickel – cadmium batteries.

Table 16 shows that the heat capacities of the nickel – cadmium batteries are of the same order of magnitude as those of lead – acid batteries, compiled in Table 14. Also here, the share of the electrolyte is a decisive factor. An exception is the heat capacity of the small button cell that is mainly determined by the metallic housing.

7.1.2.1.6. Heat Effects

Figure 80 shows heat generation in a vented nickel – cadmium battery when charged and discharged with a constant current (5-hour rate) and the charging voltage is limited to 1.65 V/cell. The calculation is based on the equilibrium voltage $U^{\mathrm{o}} = 1.3$ V and the calorific voltage $U_{\mathrm{cal}} = 1.44$ V. Due to the uncertain thermodynamic data, these calculations are only rough approximations, but correspond with practical experience.

Figure 80. Heat generation during charge and discharge of a vented nickel – cadmium battery (VARTA TS-type, values referred to 100 Ah of nominal capacity). Charging is performed with constant current I_5 (5-hour rate) until 1.65 V/cell is reached. Discharge also occurs with I_5. In the top part, sections are marked that were used to calculate the average heat generation, shown in the bottom part. (Calculation based on $U^{\mathrm{o}} = 1.3$ V; $U_{\mathrm{cal}} = 1.44$ V)

Figure 80 shows that during the initial two sections of the charging period, slight cooling is observed on account of the reversible heat effect that consumes heat at a constant rate proportional to the current. With increasing cell voltage, the Joule effect is increased, and more and more conceals the cooling effect. But the main reason of the increased heat generation at the end of the charging period is that a growing portion of the current is consumed by water decomposition. The contribution of the charging reaction with its cooling reversible heat effect is so reduced, and when the charging voltage exceeds 1.48 V/cell, water decomposition contributes a corresponding amount of heat.

During discharging, heat generation increases with decreasing cell voltage. In total 67.5 kJ of heat are produced during discharging, while heat generation during charging only amounts to 28.4 kJ. This is mainly caused by the reversible heat effect that generates additional heat during discharge, while it compensates for heat generation during charging.

The heat evolution of a sealed nickel – cadmium battery during constant-current charging is illustrated in Figure 81. A charge factor of 1.4 is applied (such an amount of overcharge is usual for conventional charging

Table 16. Typical values of the heat capacity and its share assigned to the electrolyte (1 J = 1 Ws; 1 kJ = 0.2778 Wh)

Type of battery	Heat capacity,		Percentage share of electrolyte
	$kJ\,K^{-1}\,kg^{-1}$	Wh/(K · 100 Ah)	
Stationary, 315 Ah, pocket plates	1.3	1.9	78 %
Aircraft battery, 40 Ah (vented)	0.98	0.97	48 %
Sealed round cell, 4 Ah	0.81	0.72	47 %
Sealed button cell, 0.06 Ah	0.52	0.72	41 %

methods but can only be applied to comparably small batteries < 10 Ah).

Figure 81. Charging of a sealed nickel – cadmium battery with constant current 0.2 C(A). During 7 h 140 % of the nominal capacity are recharged which corresponds with a charge factor 1.4.
For comparison, all values are converted to 100 Ah of nominal capacity. Actually, batteries of this type are in the size < 10 Ah. Larger sealed nickel – cadmium batteries can only be charged by controlled charging processes (Section 7.1.2.1.12)
Middle: current distribution between charging and internal oxygen cycle; Bottom: heat generation as an average of the different sections (slight cooling during the first 2 h)

- The voltage curve at the top shows the gradual increase of charging voltage with charging time. The generated heat is calculated as an average value for different sections of this curve. The numbers at the charging curve are the average voltages (V per cell) for the corresponding section.
- The figure in the middle depicts the (constant) current and its distribution between charging process and internal oxygen cycle.
- The bottom figure shows the heat generation as average value for the different sections. The numbers are the heat in kilojoules, converted to 100 Ah of nominal capacity for comparison.
  During the first two hours, the reversible heat effect exceeds the Joule effect and cooling is observed. Therefore the number for this section is written below the zero line.
  When the charging process approaches completion, nearly all the current is used for the internal oxygen cycle, which generates a large amount of heat.

Altogether 264.7 kJ = 73.53 Wh of heat are generated, referred to a nominal capacity of 100 Ah. Figure 81 shows that this heat is generated practically during the last 3 h of the charging process. This means an average heat generation of 24.51 W/100 Ah for these three hours. Thus, sealed nickel – cadmium batteries can be charged at a high rate as long as the current is actually used for charging and not for the internal oxygen cycle. Rapid charging methods, are always based on this principle.

Battery manufacturers usually strongly advise their customers not to operate sealed nickel – cadmium batteries at constant-voltage float charge without monitoring, because of the heat generation by the internal oxygen cycle. The fact that this cycle can attain extremely fast rates makes the situation really dangerous with respect to thermal runaway.

7.1.2.1.7. Self-Discharge

The factors that cause self-discharge of nickel – cadmium batteries are:

1) Decomposition of the charged nickel hydroxide by separation of oxygen according to

$$Ni_6O_6(OH)_6 + H_2O \longrightarrow Ni_6O_4(OH)_8 + 1/2\,O_2$$

$$[6NiOOH \approx Ni_6O_6(OH)_6]$$

With progressing reduction of the oxide, this disintegration process decreases and comes to a standstill when a stable state of oxidation is reached. Theoretically, a final oxidation state of 1.33 (Ni_3O_4) can be expected instead of 1.5 (NiOOH), which means that, at most, about half the charge would be lost. In practice however, only 10 to 20 % of capacity loss are caused by oxide decomposition.

The process is markedly increased at elevated temperature. At 40 °C, a steep decrease in capacity by nearly 20 % is observed within two days (see Fig. 82). But even at that temperature further self-discharge does not proceed to more than 22 % during 30 days.

In sealed nickel – cadmium batteries, oxygen release at the positive electrode also causes self-discharge of the cadmium electrode, since oxygen can easily reach the negative electrode where it is consumed.

2) The shuttle of a redox system always discharges both electrodes (see Section 4.2.6.2). In nickel – cadmium batteries, such a shuttle is usually caused by nitrate ions (*nitrate shuttle*), that are dissolved in the electrolyte. When they reach the negative electrode by diffusion, they are reduced to NH_4^+:

$$NO_3^- + 10\,H^+ + 8\,e^- \longrightarrow NH_4^+ + 3\,H_2O$$

The NH_4^+ ions migrate back into the electrolyte and are oxidized to nitrite when they again reach the positive electrode (the NO_3^- oxidation potential is not reached in open-circuit conditions). The cycle is repeated when the NO_2^- ions again reach the negative electrode and are reduced to NH_4^+ ions. Thus, the alternating oxidation to NO_2^- and reduction to NH_4^+ ions forms a shuttle as described in Section 4.2.6.2.

Current transport by the nitrate shuttle is effective, since six electrons are exchanged in each cycle when nitrogen is reduced from the oxidation state + 3 to − 3:

$$NO_2^- + 6\,H_2O + 6\,e^- \longrightarrow NH_4^+ + 8\,OH^-$$

Self-discharge caused by the nitrate shuttle is mainly observed in batteries with sintered electrodes, because nickel and cadmium nitrates are used in the manufacturing process to precipitate the active material into the sintered substrate. Another source of this shuttle is degradation of the polyamide separator.

3) The occurrence of short-circuits also affects both electrodes. Short-circuits can be caused by penetration of the separator by small particles washed out of the active material, or by the growth of crystal bridges between the electrodes.

4) Self-discharge of the positive electrode can furthermore be caused by hydrogen that has been evolved during overcharging of nickel – cadmium batteries at too high rates. But the effect is small, since the available amount of hydrogen is limited.

5) Self-discharge of the negative electrode occurs when oxygen penetrates into a sealed cell through a leakage (or is released at the positive electrode according to item 1). On account of the immobilized electrolyte, oxygen has access to the negative electrode surface and oxidizes cadmium according to

$$Cd + 1/2\,O_2 + H_2O \longrightarrow Cd(OH)_2$$

Quantities of Self-Discharge. Self-discharge in nickel – cadmium batteries depends largely on cell design. In general, large surface areas of the active material favor self-discharge, as do several other parameters (e.g., narrow electrode spacing) that reduce the internal resistance. So, heavy-duty cells are more susceptible to self-discharge (see, e.g., Fig. 26.11 in [157]).

In Figure 82 typical self-discharge curves are shown for vented nickel – cadmium batteries with pocket plates. Figure 83 shows curves for button cells (with pressed powder electrodes and comparatively high internal resistance) and cylindrical cells with sintered electrodes. Both figures illustrate the enormous influence of battery design on the self-discharge rate.

Figure 82. Charge retention of a vented nickel – cadmium battery with pocket plates at different temperatures (Vantage Battery of ALCAD Ltd. [158])

Figure 82 also shows the strong increase of self-discharge at 40 °C. This initial steep part of the curves is mainly caused by decomposition of the nickel hydroxide.

The strong influence of temperature on the self-discharge rate in both examples of Figure 83 is mainly caused by the usual acceleration of electrochemical reactions, but may also have been increased by separator hydrolysis.

The self-discharge rate can also be influenced by additives. Cobalt addition to the nickel hydroxide, for example, reduces self-discharge at elevated temperatures.

7.1.2.1.8. Types of Electrodes

Compared to the grid of lead – acid batteries, much more variety is possible in the construction of nickel – cadmium batteries, since the corrosion of nickel usually is negligible. Thus, thin layers, sintered bodies of high porosity, or foam-like structures of nickel can be used as stable substrates in the positive electrode. Nickel can also be used as conducting or supporting material in negative electrodes, despite the comparatively low hydrogen overvoltage of nickel, since the potential of the electrode is determined by the slightly positive $Cd/Cd(OH)_2$ potential, and hydrogen evolution is only possible when the negative electrode is correspondingly polarized.

Figure 83. Capacity loss during storage of sealed nickel – cadmium batteries
A) Button cells, Varta DKZ [159]; B) Cylindrical cells, Sanyo N-Type (Fig. 4.1 in [160])

Pocket electrodes are in widespread use in vented nickel – cadmium batteries (see Fig. 84). They consist of strips of perforated nickel-plated iron that form "pockets", filled with the active material ([153], p. 59 f). A number of such strips is assembled to a flat plate. Positive and negative electrodes usually contain graphite as a conducting aid. In "genuine" sealed nickel – cadmium batteries, pocket plates are not used, but in so called "ultra-low maintenance batteries" as shown in Figure 84. The latter are flooded nickel – cadmium batteries. But they take advantage of the internal oxygen cycle, although limited to small rates, to reduce water loss. The vent cap that allows gas exchange in both directions is replaced by a valve through which gas only can escape.

Figure 84. Schematic construction diagram of an "ultra-low-maintenance battery" (1.2 V single cell). Such batteries with limited internal recombination are available in nominal capacities between 8 and 476 Ah.
They are offered as monoblocks up to 12 V per block (AL-CAD Vantage [161])

Figure 84 shows the arrangement of the pocket plates that corresponds to the plate group in Figure 68. The valve has an opening pressure of about 2×10^4 Pa. The battery is filled with liquid electrolyte. The separator is a polypropylene fibrous material that is claimed to support the oxygen diffusion from the positive to the negative electrodes. An efficiency of the internal oxygen cycle between 85 and 95 % is observed at low float voltages and correspondingly low currents. Otherwise, the limited oxygen transport rate reduces this efficiency. Presumably a considerable share of the oxygen reduction occurs at the conducting parts that are not immersed into the electrolyte, but are in contact with the fibrous separator which is wet with electrolyte.

Pressed electrodes are mainly used in button cells (Fig. 85). Thin tablets of the active material are pressed and enclosed in a nickel-wire gauze that simultaneously provides mechanical support and acts as a current collector (in Fig. 85 sections of the wire gauze are removed from both electrodes to show the active material). The conductivity of the active material itself is improved by the addition of nickel powder. In this example, one pair of pressed electrodes forms the plate group. Stacks of several parallel electrodes are occasionally used to increase the electrode surface.

Figure 85. Construction of a button cell (VARTA)

The upper electrode in Figure 85 is the negative one; the positive electrode can be seen at the bottom. The separator is a felt disk between the electrodes. It consists of a nonwoven fiber felt of polyamide or polypropylene.

The cup of the nickel-plated steel casing acts as the positive terminal. The steel spring between the negative electrode and the cup provides the desired pressure for the separator and compensates for swelling, especially of the positive electrode. Furthermore, the spring forms void space for fast oxygen transport to the surface of the negative electrode.

Sintered electrodes are based on carbonyl nickel, an extremely fine powder produced by thermal decomposition of nickel tetracarbonyl, $Ni(CO)_4$. The powder is sintered at about 1000 °C. The result is a spongy sintered body with fine pores and a porosity of about 80 vol %.

Sintered plates can be manufactured with a thickness of up to several millimeters, but nowadays fairly thin plates are generally used with a thickness in the range of 0.5 to 1 mm. The core of the plates is a perforated, nickel or nickel-plated iron strip (0.05 to 0.1 mm thick) coated on both sides with the sintered nickel. Such electrodes normally are manufactured by a continuous sintering process [162].

The sintered plates are filled with the active material by different methods. Always, the sintered substrate is first soaked by the dissolved active material that subsequently is precipitated within the pore system. Otherwise, it would not be possible to fill the fine pores. Furthermore, a close contact between the substrate and the active material is achieved by such a precipitation. High utilization of the active material is so attained between the thin layer of active material on the large surface of the current-conducting substrate and also by the fact that the surface of

the electrode is not partly covered by the conducting material, as in pocket plates.

Chemical impregnation is used by most manufacturers. The sintered substrate is inserted into a tank, which is evacuated and then filled with nickel nitrate solution when positive active material is impregnated, or with cadmium nitrate solution when negative electrodes are processed. Temperatures between 50 and 80 °C are applied, and the sintered material is soaked completely with the solution of the nitrate, i.e., $Ni(NO_3)_2$ or $Cd(NO_3)_2$

After drying with steam, the soaked material is transferred to a tank which is filled with aqueous sodium hydroxide. When positive electrodes are processed, the impregnation of the nickel hydroxide occurs according to:

$$Ni(NO_3)_2 + 2\,NaOH \longrightarrow Ni(OH)_2 + 2\,NaNO_3$$

The negative electrode is impregnated by the following reaction:

$$Cd(NO_3)_2 + 2\,NaOH \longrightarrow Cd(OH)_2 + 2\,NaNO_3$$

After completion of these reactions the impregnated substrate is rinsed thoroughly with water and dried.

The described sequence is repeated four to eight times, depending on the type of electrode and the amount of active material required in the plate. Additives like cobalt or cadmium are added to one or several of these impregnation steps. Sintered plaques produced as single plates can be impregnated similarly.

Electrochemical impregnation is another possibility for filling the sintered substrate with active material. Electrochemical impregnation is also based on $Ni(NO_3)_2$ or $Cd(NO_3)_2$ solutions, but the precipitation is achieved by a cathodic current that changes the pH value of the solution [163].

Electrochemical impregnation has been revised and improved repeatedly [164]. It has not gained the importance of chemical impregnation, but it is used occasionally for electrodes based on fiber supports.

Thermal decomposition is a third way to fill the positive active material into the sintered substrate (cf. [153, p. 129]). The substrate is soaked with $Ni(NO_3)_2 \cdot 6\,H_2O$, which then is subjected to thermal decomposition at 180 to 250 °C. More recent variations of this method are described in [165].

Sintered electrodes are used in prismatic cells where they form plate groups as shown for a lead – acid battery in Figure 68 (see also Fig. 86). Mostly they are used in cylindrical cells as shown in Figure 88.

Foam Electrodes. Foam substrate is used for positive electrodes of high specific capacity. The basis is foamed polyurethane resin that is plated with nickel. After plating, the polyurethane is removed by burning and a nickel skeleton is left with about 95 % of void space (porosity) [166].

The active material is usually filled as a paste into this framework of nickel. The final thickness of the plate is achieved by pressing after pasting and drying.

Fiber Electrodes. Repeated efforts have been made to replace the fairly expensive sintered substrate. The *composite nickel electrode* is one result. Felts of graphitic-fiber material are coated with a layer of nickel of the thickness 0.6 to 0.8 µm. These coated fibers are sintered together and then welded to a supporting thin nickel grid (usually of expanded metal). The completed plate is impregnated by the electrochemical process described above [167]. The advantage of this electrode is that it is lighter than the sintered type.

Fiber or *felted support structures* are manufactured by precipitation of a nickel layer onto specially prepared fibers. The organic or carbon fibers are left underneath the nickel coating or are removed by thermal decomposition [168]. The porosity of fiber supports is 85 – 90 vol %.

The advantage of electrodes based on fiber substrates is that they can be manufactured with thicknesses between 0.6 and 10 mm with approximately constant performance features, because the conducting substrate increases with electrode thickness. The substrate retains also some flexibility even when the fibers are coated with nickel, and this flexibility helps when the active material swells.

The fiber substrate itself can be used as an auxiliary electrode to increase the oxygen-reduction rate [169], [170].

Figure 86 shows such a cell. The arrangement of the electrodes can be seen in the opened part: a negative electrode in the foreground is accom-

panied by an auxiliary electrode made of nonimpregnated fiber felt to improve the rate of oxygen reduction. The terminal on the right is connected with the positive electrode. The plate lugs are bolted, as usual in larger nickel – cadmium batteries of the vented type.

Figure 86. Sealed nickel – cadmium battery (1.2 V, 19 Ah nominal capacity) with fiber structure electrodes and auxiliary fiber mats for oxygen reduction (Daug/Hoppecke)

The increased oxygen-reduction rate allows fast recharge of the battery. But for thermal reasons this can only be done under controlled charging conditions.

Plastic-bonded negative plates were also developed to replace the expensive sintered electrodes. The active material is mixed with 5 to 10 wt % of polytetrafluoroethylene (PTFE) and pressed or rolled on a substrate, usually a nickel-wire net [171]. Plastic-bonded electrodes are mainly used for larger batteries in traction applications.

To achieve sufficient porosity of these active materials, graphite has to be added, which forms a fine pore system and simultaneously increases the conductivity [172]. Plastic-bonded electrodes are applied only as negative plates, since graphite would be oxidized in the positive electrode and form carbonate.

Electrodeposited (Negative) Electrodes. The cadmium electrode can also be made by galvanic precipitation of cadmium on a nickel or nickel-plated steel strip, similar to that used as substrate for the sintering process [173]. The metal strip is passed through a bath containing Cd^{2+} ions while it is connected to the negative pole of a rectifier. The positive electrode in this bath consists of metallic cadmium, which is dissolved when the current flows.

The current density has to be adjusted so that the precipitation of cadmium and evolution of hydrogen occur simultaneously and form a spongy cadmium layer, which by rolling is compressed to the desired thickness.

7.1.2.1.9. Cell Design

Prismatic cells are available in the vented and the sealed design. Examples of larger cells are shown in Figures 84 and 86. But small types are also offered, comparable to the prismatic cell in Figure 98.

Vented cells types (available in the range 7.5 to 1250 Ah) are usually equipped with pocket plates like the example shown in Figure 84. Smaller types are provided with containers of polystyrene or steel, while the larger types mostly have containers of stainless steel. The plates are spaced by nets or a number of rods, both of plastic material. Separators, as in the sealed version, are not required, since the active material is stabilized by the perforated steel stripes that form the pocket.

Batteries of this type are mainly used for stationary applications, as standby batteries or for diesel cranking. They are preferred in cold climates where lead – acid batteries are endangered to freeze, and in hot climates where lead – acid batteries suffer from increased corrosion.

For high load applications, vented nickel – cadmium batteries are also offered with sintered plates. An example are air-craft batteries as shown in Figure 87.

Air-craft batteries are designed for high load at minimum weight and volume. Figure 87 shows a typical nickel – cadmium aircraft battery. The plates are spaced by a felt of polyamide, and the distance between the plates is kept as small as possible. A membrane of cellophane prevents direct access of oxygen to the negative electrode. The limited amount of electrolyte affords frequent refilling of water, but this draw-

back is outweighed by the comparatively low weight and volume.

Figure 88. Cross-section of a sealed cylindrical nickel – cadmium battery (Panasonic) [174]

Cylindrical cells are widely used as sealed cells for power supply, mainly for portable devices, when capacities are required between 150 mAh and about 5 Ah. Nearly all types of electrodes, i.e., sintered, fibers, foam, and plastics electrodes are employed in this cell design.

The characteristic constructional features of cylindrical cells are shown in Figure 88.

A positive and a negative electrode are spirally wound together with the separator between them. A nickel-plated steel case encloses the electrode group and withstands the fairly high internal pressures that may occur during overcharge. The case acts as the negative terminal. A flat button in the cover is the positive terminal. The lateral face of each cell is usually covered with a shrink sleeve of plastic to prevent short-circuits.

Inside the cell, both electrodes are equipped with a number of metal strips that act as current conductors. The strips of the positive electrode are welded to the cover. The negative electrode is connected in a similar way with the bottom of the cell case.

The cell shown in Figure 88 is equipped with a resealing valve based on the compression of a rubber pad (see Section 7.1.2.1.11, especially Fig. 91).

The performance data required by the varying applications are very different and cannot be achieved by one "universal" battery design. So, most manufacturers offer several series of cylindrical sealed nickel – cadmium batteries. Such basic types are:

- *Standard types*, which represent the most economic solution.
- *High-current types*, characterized by low internal resistance, mainly achieved by a special design of the conducting elements within the cell. They are used for high-load applications like motor drives.

– *High-capacity batteries*, specially designed for high loads. They combine a maximum amount of active material with low internal resistance.
– *High-temperature batteries*, characterized by stabilized active material in the positive electrode, achieved by an increased cobalt content and by heat resistant separators. They may comprise an electrolyte that contains sodium hydroxide to reduce leakage. Emergency lighting is one field of application.
– *Fast-charge types*, suitable for recharging within one hour or less. This feature is mainly demanded for cordless tools. Fast charging is achieved with layers of active carbon which are rolled onto the surface of the negative electrode and increase the rate of oxygen reduction. But this "auxiliary electrode" requires volume that cannot be used for active material. So, maximum capacity cannot be achieved with this design.
– *Memory-backup batteries* are used for standby operation (memory backup) frequently at elevated ambient temperatures. Often they are directly soldered to printed circuit boards and therefore have to be leakproof for a long service life. Such batteries are equipped with temperature-resistant separators, special seals that prevent leakage, and often they contain a sodium hydroxide electrolyte. The advantage of the sodium hydroxide electrolyte is its reduced tendency to seep out of the seal. The main field of application is the protection of electronic memories. As a consequence of the reduced conductivity of the electrolyte, the internal resistance is somewhat higher than that of the aforementioned types.

Button cells (see Fig. 85) are in widespread use as small energy sources at moderate loads in pocket computers and similar applications.

7.1.2.1.10. Cell Assemblies, Power Packs

In general, sealed nickel – cadmium batteries are not used as single cells, because of the higher voltage usually required. For this reason, several cells are usually assembled for a battery. There are many ways of arranging the cells in a battery. Some examples of possible combinations of cylindrical cells are shown in Figure 89.

Figure 89. Examples for the connection and fixing of cylindrical cells that are assembled to multicell batteries, also called "power packs" (Sanyo Cadnica [175])

The upper line in Figure 89 shows various ways to connect cells. Contact between the individual cells is achieved by spot welding with corresponding tags. The battery on the right-hand side, that is formed by stacking the cells, is mainly used for smaller cells. Sometimes two or more strings form a slim battery that can be placed in the handle of tools. To avoid short circuits, the battery usually is covered completely by insulating plastic material, except for the soldering tags.

Mostly, power packs are completely encapsulated by plastic material, as shown on the right-hand side in the lower line of Figure 89. Such packs are offered in a wide variety since a battery often is tailored to its application. The fast growing market for cordless telephones, tools, camcorders, and toys caused a nearly indeterminable variety of batteries.

The cells that are combined in a battery pack usually are matched for capacity. Otherwise, individual cells may suffer deep discharge or inadmissible overcharge. This is true especially for batteries operating in rigorous conditions, e.g., in tools. In regard to such a matching, the customer should not combine single cells in batteries himself, especially in the case of heavy-duty batteries.

Button cells are also combined to batteries. Often they are stacked and enclosed by a shrink sleeve, but the are also available encapsulated by plastic containers as batteries of different shape.

7.1.2.1.11. Valve Design

Nickel – cadmium batteries can be sealed completely. In theory, this battery system should

need no valve. Nevertheless, for safety reasons, also nickel – cadmium batteries usually are equipped with valves to prevent explosion from unexpected increase of internal pressure, usually caused by abuse of the battery, e.g., during overcharge with a too high current.

Two kinds of valve are used:

- Genuine "safety vents" destroyed in an emergency,
- Resealing valves, which open at a certain overpressure but close again when the internal pressure drops below the critical value.

An example of the first kind is shown in Figure 90. The sealing element is a metallic membrane which bulges upwards with increasing internal pressure (diaphragm in the figure). A pointed piece of metal is bent down from the outer cell cover, and its point pierces the membrane when its bulge is excessive.

Figure 90. Safety vent in a cylindrical sealed nickel – cadmium battery ([153, Fig. 2.59, p. 212], reprinted by permission of The Electrochemical Society, Inc.)

Safety vents as in Figure 90 were used mainly during the first decades of the manufacture of sealed nickel – cadmium batteries. Absolutely tight sealing can be achieved with this vent. But as soon as the membrane is pierced, the sealing is completely destroyed. Then the cell operates like a vented all, which means that water loss ends the service life within a short time. Thus, an occasional overcharge might spoil the whole battery.

For this reason, safety vents as in Figure 90 have been largely replaced by resealing valves. Today, the safety vent, as described in Figure 90, is used only with batteries that have to be sealed absolutely, e.g., for space application or with button cells where a point of fracture in the cup acts as a safety vent.

Improvement of elastomers (synthetic rubber), enabled the development of simple and also reliable resealing valves. One example of various similar designs is shown in Figure 91.

Figure 91. Resealing valve for nickel – cadmium batteries based on a compressed rubber part

The shaped rubber part is pressed on a seat in a metallic cap that is welded on top of the cell cover. This cap is welded only at certain points, and slots are left for the gas to escape between the cell cover and the metallic cap. When the internal pressure exceeds the critical value, the rubber part is compressed so much that a slot is formed between the steel cover and the rubber, and the gas can escape.

The advantage of the resealing valve is obvious: occasional abuse of the battery causes some water loss; but, if this loss is limited, it will not influence the performance significantly. The battery will operate as before and can reach the usual service time. Hydrogen that has been evolved will even be gradually removed by oxidation at the nickel surface in the positive electrode.

A disadvantage of the resealing valve is that it cannot be sealed as perfectly as the safety vent in Figure 90. However, for usual battery applications the advantages outweigh the disadvantages. Especially in batteries composed of a larger number of cells, occasional overcharging or overdischarging (reversal) of single cells often cannot be excluded. In such cases, the battery as a whole is better protected by resealing valves, when the damage of the concerned cells does not exceed certain limits.

7.1.2.1.12. Controlled Charging

A simple charging method for sealed nickel – cadmium batteries is shown in Figure 81. But it takes about 14 h for complete recharge, and for many applications, e.g., in tools, a short charging period is desired. Acceleration of the charging process can be achieved by an increased charging current. But inadmissible overcharging has to be avoided, which means that the charging current has to be reduced as soon as the cell reaches a certain stage

Figure 92. Cell voltage, cell temperature, and internal pressure of a sealed nickel – cadmium battery versus charging time during recharge at 1 C(A) (1-hour rate) [176]

of recharge. So additional parameters are required to determine this critical stage of the charging process. Such parameters are:

- *Amount of charge*, measured directly or calculated as the product of charging current and charging time. One simple method that uses this parameter, is to discharge the battery completely before the charging process starts. Subsequently the amount of current is charged that is required for a complete charge.
- *Cell temperature* increases significantly when the internal oxygen cycle has started. Temperature sensors can be used to terminate the charging process.
- *Cell voltage* is an often used parameter. Cell voltage decay at a constant current is caused by reduced polarization of the positive electrode due to increased heat generation when the internal oxygen cycle starts. The voltage decay thus indicates that the positive electrode is fully charged. If the charging current is not constant, the varying voltage drop has to be considered, e.g., by measuring the cell voltage during periods of current interruption.
- *Internal pressure* also reflects oxygen evolution at the positive electrode. Its measurement is, however, rather expensive and hardly applied in practice.

The behavior of the three parameters: cell voltage, cell temperature, and internal pressure during constant-current charge is shown in Figure 92. All three parameters are plotted versus charging time during recharge at 1 C(A) ($\approx$ 1-hour rate).

The cell voltage increases with charging time and reaches a maximum shortly after about 100 % of the nominal capacity has been restored. But the battery is not recharged completely at this point, because a portion of the current has been used for the internal oxygen cycle. The subsequent decline of the cell voltage is caused by the rising cell temperature, mainly on account of the increasing current share that is consumed by the internal oxygen cycle. This increasing temperature accelerates the oxygen-evolution reaction at the positive electrode and thereby reduces its polarization. The resulting voltage decay ΔU is often used to terminate the charging process as indicated in Figure 93.

This voltage decay would be dangerous if the battery were charged at constant voltage. The more and more reduced polarization would continuously increase the current and so result in a further increasing temperature. If no other parameter terminates the charging process, this situation would finally lead to thermal runaway.

The temperature curve in Figure 92 shows a slight decrease during the first stage of the charging process, caused by the negative reversible heat effect. With the onset of the internal oxygen cycle, heat production is increased corresponding to Figure 81 and the cell temperature rises.

The internal pressure is related to the balance between the oxygen-evolution rate at the positive electrode and the oxygen-reduction rate at the negative electrode and mainly determined by the transport rate of oxygen.

Fig. 93 shows a number of parameters that are used in controlled charging methods.

Figure 93. Charging characteristics that are used in controlled charging methods for nickel – cadmium and nickel – metal hydride batteries [177]

Cell temperature: at the time t_a the voltage U_t is reached that is below the maximum voltage U_p and even below the voltage that finally would be reached. By that time, about 70 % of recharge is achieved, and the thermal situation of the cell is still stable. Ut is often used to reduce the high initial charging current so far that thermal risks are excluded during the final charging period.

Cell voltage decay: the cell voltage decay ΔV that is reached at the time t_b is frequently used to terminate the charging process.

Turning point α of the differential of the temperature curve dT/dt: this turning point, reached at the time t_d, is caused by the increased heat dissipation due to the increase of the cell temperature. It is used to reduce the charging current or switch to a short additional charging period.

Cell temperature: The cell temperature Tt that is observed at the time t_c is mainly used as an additional parameter to cut the charging current when other controlling mechanism have failed. This parameter is not suited for direct control of the charging, since it is observed too late.

7.1.2.2. Nickel – Hydrogen Batteries

Nickel – hydrogen batteries, known also as hydrogen – nickel oxide batteries, have been developed for aerospace applications and are still the number one energy storage system in many satellite projects [178]. This system employs the same positive electrode and also the same electrolyte as the nickel – cadmium battery. But for the negative electrode hydrogen is used as active material instead of cadmium. Furthermore, the negative electrode is different from a conventional battery electrode and corresponds to a fuel-cell electrode. The electrode material is not transformed, but acts only as a catalytic surface that provides or absorbs the electrons.

The catalytic effect of the negative electrode is not a pure surface effect, it rather includes absorption and the formation of metal hydrides. But, the amount of platinum or palladium, used in such batteries, is so small that the storage capacity of the electrode has no relevance.

Hydrogen is not stored in the electrode. In the charged state of the battery, it remains as gaseous hydrogen within the cell. The container therefore has to withstand pressures up to about 50 bar. On account of the hydrogen storage, nickel – hydrogen batteries must be hermetically sealed.

The discharge reaction of the negative electrode is:

$$H_2 + 2\,OH^- \longrightarrow 2\,H_2O + 2\,e^-$$

Its reversal (from right to left) represents the charge.

The generation of gaseous hydrogen during charging and its consumption during discharging means that the internal gas pressure is proportional to the state of charge. This offers the possibility to check the state of charge by measurement of the internal cell pressure.

Usually platinum is applied as electrode material on account of its outstanding catalytic capabilities and its chemical stability. Platinum is usually bonded by polytetrafluoroethylene (Teflon) or covered with microporous Teflon membranes to make the surface hydrophobic and so prevent the formation of thicker layers of water that would hinder gas access. The electrolyte is immobilized by soaking up in fiber felts or knitted textiles of mineral fibers (fuel-cell grade asbestos paper) or zirconia fibers stabilized with yttria (Zircar cloth). They provide high temperature resistance and chemical resistance for long-life batteries.

Combination with the reaction of the nickel electrode (Section 7.1.2.1.2) leads to the cell reaction (discharge from left to right)

$$2\,NiOOH + H_2 \longleftrightarrow 2\,Ni(OH)_2$$

During discharge, NiOOH is reduced to $Ni(OH)_2$ and hydrogen is consumed. During charge, this equation is reversed. Hydrogen is stored in each cell as gas. Figure 94 shows a sectional view.

Thermodynamic Situation, Secondary Reactions. The thermodynamic situation of the nickel – hydrogen battery is shown in Figure 95. It is similar to that in the nickel – cadmium battery shown in Figure 78. The positive electrode is identical, while at the negative electrode the charging reaction is hydrogen evolution (H^+ oxidation):

$$2\,H_2O + 2\,e^- \longrightarrow H_2 + 2\,OH^-$$

and the charging reaction its reversal:

$$H_2 + 2\,OH^- \longrightarrow 2\,H_2O + 2\,e^-$$

The equilibrium potential of the hydrogen electrode is only 0.02 V lower than that of the cadmium electrode. Thus, the cell voltage is $U^o = 1.34$ V, in practice $U^o \approx 1.3$ V.

Oxygen evolution, oxygen reduction, and the internal oxygen cycle occur as in nickel – cadmium batteries. If no current flows through the cell, any oxygen that had been generated within the cell is removed by direct catalytic recombination of oxygen and hydrogen, because at the negative electrode a mixed potential is formed between hydrogen oxidation ($H_2 \longrightarrow 2\,H^+ + 2\,e^-$) and oxygen reduction.

Hydrogen oxidation is the discharge reaction at the negative electrode. But due to its high pressure, hydrogen is also oxidized at a perceivable rate at the positive electrode as an unwanted secondary reaction, that reduces the efficiency of the charging reaction and acts as a parasitic discharging reaction during discharge. At open circuit, reduction of nickel hydroxide is the counter reaction; and self discharge according to

$$2\,NiOOH + H_2 \longrightarrow 2\,Ni(OH)_2$$

is the result. This direct reaction between H_2 and Ni(OOH) causes the considerable self-discharge rate of nickel – hydrogen batteries. An *internal hydrogen cycle* is established when the battery is discharged so deeply that hydrogen is evolved at the reversed nickel hydroxide electrode. This hydrogen subsequently is oxidized at the negative electrode according to the normal discharge reaction: So, the negative electrode is not reversed, but remains at its normal discharge potential, while H_2 is now supplied by the reversed positive electrode. This internal hydrogen cycle allows deep discharges that include the reversal of individual cells.

Advantages of the nickel – hydrogen battery system are:

- A fairly high specific energy of 50 to 60 Wh/kg depending on design and size.
- The ability to withstand a great number of deep discharges (40 000 cycles at 40 % DOD).
- A service life of 15 years.
- The battery can be deeply discharged and single cells reversed without damage.
- The state of charge can easily be controlled by measurement of the H_2 pressure.
- Each cell is hermetically sealed. No maintenance is required.

Disadvantages are:

Figure 95. Equilibrium potentials of the negative and positive electrodes in nickel – hydrogen and nickel – metal hydride batteries, and current – voltage curves for O_2 and H_2 evolution, O_2 reduction, and H_2 oxidation.
For the x-axis, the electrode potential, two scales are employed: The upper one represents the potential E_h referred to the hydrogen electrode in the same solution (HESS), the lower scale E_o referred to the standard hydrogen electrode (SHE) for 1.250 g/cm^3 density of the KOH solution at 25 °C. (cf. Fig. 72)

– Its high price which limits the application more or less to aerospace projects. (More recently, efforts have been made [179] to reduce the price and develop a nickel – hydrogen battery also for remote terrestrial applications like photo-voltaic stations).
– High self-discharge rate of about 5 % per day at room temperature, due to direct reaction between hydrogen and nickel.
– The energy density amounts to only 20 to 40 Wh/L, because of the volume required for gas storage and the shape of the pressure vessel.

The above listed advantages explain the widespread use in the aerospace field.

Low-Pressure Nickel – Hydrogen Battery. A modified version of this system is the low-pressure nickel – hydrogen Battery. It has in principle the same design as the normal nickel – hydrogen battery, but hydrogen is stored as a metal hydride in alloys as they are used in nickel – metal hydride batteries. The advantages are that the container must not withstand high pressure and the rate of self-discharge is lower. On the other hand, the alloy contributes additional weight.

7.1.2.3. Nickel – Metal Hydride Batteries

The nickel – metal hydride battery is based on the same reactions as the nickel – hydrogen battery. But in nickel – metal hydride batteries, special alloys act as the catalytic electrode surface and simultaneously absorb H_2 by forming metal hydrides under low pressure. Thus the negative electrode material catalyzes the reaction and simultaneously stores the hydrogen that is formed during charging.

7.1.2.3.1. Thermodynamic Parameters

For the cell reaction

$$2\,(\beta\text{-NiOOH} \cdot H_2O) + H_2 \longleftrightarrow 2\,Ni(OH)_2 + 2\,H_2O$$

the free enthalpy of reaction ΔG is -259 kJ and the reversible heat effect $Q_{rev} = T\Delta S = -36\,kJ$. Q_{rev} is very close to that of nickel – cadmium batteries (Section 7.1.2.1.4).

But here, heat effects have also to be considered that are caused by hydrogen absorption and desorption in the material of the negative electrode. Hydrogen absorption is an exothermic reaction and supplies additional heat during charging. The quantity of heat depends on the alloy applied for hydrogen storage. It might compensate or even over-compensate the reversible heat effect. For this reason, the characteristic feature of nickel – cadmium and nickel – hydrogen batteries that the charging reaction causes cooling of the battery, may not apply to nickel – metal hydride batteries, (see, e.g., [180]).

The equilibrium voltage U^{o} is the same as that of the nickel – hydrogen battery, $U^{o} \approx 1.32$ V, and also its temperature coefficient $U^{o}/dT \approx 0.6$ mV/K. Both values almost correspond to those of the nickel – cadmium battery system.

The fairly high value for the specific energy of 387 Wh/kg effected by the cell reaction, is markedly reduced by the required weight of the storing alloy. So this quantity is lowered to about 300 Wh/kg as shown in Table 13.

7.1.2.3.2. Hydrogen-Absorbing Alloys

(→ Hydrogen, Chap. 9.3.1.2.; → Hydrides, Chap. 5.)

Hydrogen can be stored at a fairly low pressure when it is absorbed by metals which form hydrides. Palladium, for example, absorbs between 0.4 and 2 wt % of hydrogen. This means that 1 cm^3 palladium is able to store up to 1200 cm^3 of gaseous H_2 at 25 °C and 1 bar. This demonstrates the enormous hydrogen storage capability of such metal hydrides.

Less noble metals are also able to form hydrides and to store considerable amounts of hydrogen, and a great variety of such elemental hydrides exists. But most of them are of little practical use, since only a few hydrides offer a reasonable hydrogen equilibrium pressure at room temperature. This situation changed when intermetallic compounds were developed that combine elements that form strong hydrides with those that form weak hydrides. Such intermetallic compounds are alloys of two or more metallic elements, having narrow integer stoichiometries. The number of possible intermetallic compounds is nearly unlimited, and a great number of alloys have been discovered or developed that form metal hydrides [181], providing hydrogen storage in a suitable range of pressure and temperature (surveys are given in [182]). The intermetallic compounds are divided into groups $A_{\mu}B_{\nu}$, based on composition and crystal structure. A represents a strong hydride forming element and B the weak hydride forming component. For practical purposes A and B often are combinations of various elements as shown in Table 17.

Combinations that proved to be suited for hydrogen storage in batteries are known as AB, AB_2, A_2B and AB_5 (see, e.g., [184]). Table 17 shows their characteristic composition and some features.

AB_5 alloys are nowadays mainly used for batteries. Mischmetals are mostly substituted for lanthanum, mainly because they are less expensive than pure La. But such substitutions also are required to stabilize the alloy and prevent its premature degradation.

The AB_2 type in row 2 of Table 17 is based on vanadium, titanium, zirconium, and nickel. Especially for these intermetallic compounds the stoichiometry is not well defined. So, some alloys ascribed to this group may be named A_2B or AB as well. They often have the crystallographic structure of Laves phases and are called Zr – Ni – V – Cr multicomponent alloys (e.g., the *Ovonic alloys* [187]).

Titanium – nickel intermetallic phases (A_2B and AB type) were developed in the 1970s with great assiduity for hydrogen storage in road vehicles with hydrogen combustion engines [191].

Figure 96 shows pressure – composition isotherms of an AB_5 alloy ($LaNi_{4.7}Al_{0.3}$). For each temperature the upper and lower curves denote absorption and desorption, respectively. Initially hydrogen is absorbed with increasing pressure, until the formation of the MH_n phase starts. Then the pressure remains approximately constant, until the metallic phase is converted into hydride. Desorption of hydrogen occurs at lower pressure and the hysteresis between absorption and desorption pressure indicates the energy loss between absorption and desorption. The horizontal axis is given in moles hydrogen per mole metal. So the ratio 1 means 6 H per alloy formula, or, with the molecular masses of La, Ni, and Al = 138, 59, and 27 respectively, 6 g hydrogen per 423 g of alloy. This gives a storage

Table 17. Classes of intermetallic compounds that are used for negative electrodes of nickel – hydride batteries; alloys corresponding to rows 1 and 2 are nowadays mainly applied

	A_uB_v Class (basis)	Actual components	Storage capability, Ah/kg	Remarks
1	AB_5 ($LaNi_5$)	A: mischmetal ∗, La, Ce, Ti B: Ni, Co, Mn, Al	≈ 300 at max. (e.g., [185])	at present, mostly used alloy group
2	AB_2 ($TiNi_2$)	A: V, Ti B: Zr, Ni (+ Cr, Co, Fe, Mn)	≈ 400 at max. (e.g., [186])	basis of "multi-component alloys" [187]
3	AB (ZrNi)	A: Zr, Ti B: Ni, Fe, Cr, V		early used for hydrogen storage in cars and as electrodes [188], [189]
4	A_2B (Ti_2Ni)	A: Mg, Ti B: Ni		

∗ Mischmetal (Mm) is an unrefined rare earth mixture (mainly Ce, La, Nd, and Pr) (→ Cerium Mischmetal, Cerium Alloys, and Cerium Compounds). Its composition depends on the ore [184], but "synthetic mischmetals" are also known [190].

capability of about 1.4 wt %. In electrochemical equivalents 6 g of H_2 mean 3 times 53.6 Ah or 160.8 Ah per 423 g which equals 380 Ah/kg that are stored in this case.

Figure 96. Pressure – composition isotherms (PCI curves) of an AB_5 alloy with nickel partly substituted by aluminum ($LaNi_{4.7}Al_{0.3}$) (Fig. 2.18 in [192])

The hydrogen storing alloys are usually not manufactured in battery plants, but are provided by specialized suppliers (some references are given in Section 2.5 of [192]). Selection of the raw materials and preparation of the hydrogen absorbing alloy are most important, because not only the composition of the alloy but also its structure and the distribution of the alloying elements are decisive for capacity and service life [193].

In the battery, the hydrogen storing alloy is in direct contact with the electrolyte and also acts as the electrode. So the interface layer has to resist corrosion and oxidation attacks and may undergo significant structural and compositional changes [194]. This layer plays an important role: While the bulk of the electrode material determines the capability for hydrogen absorption and so the capacity, the interface layer is decisive for most performance data, e.g., high rate discharge capability and cycle life.

The performance characteristics of nickel – metal hydride batteries are very similar to those of sealed nickel – cadmium batteries. The cell voltage differs by only 20 mV, and charging as well as discharging performance are so alike that both battery systems can replace each other in all normal applications. The discharge curves in Figure 97 confirm this: they differ from each other only by the discharge duration.

Figure 97. Comparison of discharge voltage and capacity between nickel – cadmium and nickel – metal hydride batteries of the same size [196]
Cylindrical cells, AA type (Mignon cell), discharging current 0.2 CA (≈ 5 h)

In general, metal-hydride electrodes are inferior to cadmium electrodes at extremely high rates and low temperatures, because of the reduced rate of hydrogen desorption. In prac-

tice, however, discharge performance under these conditions is mainly a question of electrode thickness. Thus, such a comparison depends largely on the special battery design, and nickel – metal hydride batteries with thin electrodes can give a better performance at low temperatures than nickel – cadmium batteries with thicker electrodes.

Self-discharge in nickel – metal hydride batteries is based on hydrogen oxidation as has been described for nickel – hydrogen batteries (Section 7.1.2.2). But, due to the low hydrogen equilibrium pressure, the rate of self-discharge is reduced so far that it only attains rates known for nickel – cadmium batteries.

7.1.2.3.3. Design

Due to similar cell voltage and discharge/charge behavior, nickel – metal hydride batteries can replace nickel – cadmium batteries. For this reason, they are manufactured in the same dimensions. Button, cylindrical, and prismatic cells are offered, but also battery or power packs and "smart batteries".

For the positive electrode, usually foam electrodes (see Section 7.1.2.1.8) are applied, to balance the comparatively large capacity of the hydrogen storage electrode.

Constructional details of cylindrical and small prismatic nickel – metal hydride batteries are shown in Figure 98. The arrangement of the electrodes in cylindrical cells is similar to that of cylindrical lead – acid and nickel – cadmium batteries (Figs. 70, and 88 respectively). In the prismatic cells, a number of positive and negative electrodes are paralleled and form the plate group as in Fig. 68.

The electrode assemblies are inserted into a nickel-plated steel can. The can acts as the negative pole, while the lid is the positive terminal, both are insulated by a plastic gasket. The cell is sealed by crimping the lid to the can. Perfect sealing is of great importance because of the volatility of hydrogen. The lid contains a resealable valve similar to that described in Figure 91. As in the case of nickel – cadmium batteries, this valve opens only in an emergency to prevent inadmissible pressure increase. In normal operational conditions the nickel – metal hydride battery remains completely sealed, and hydrogen does not escape.

Due to their high specific energy content and their capability of high discharge rates and rapid charging, nickel – metal hydride batteries are promising candidates as storage systems for hybrid electric vehicles that combine an ignition engine with electric drive. Longer distances are covered by the gasoline engine, in the cities the vehicle is driven by battery power. This requires a comparatively small battery that can be heavily loaded. Figure 99 shows such a module. The fan belongs to the air cooling system.

The expected cycle life of these batteries is $\geq$ 2000 cycles (100 % DOD).

Nickel – metal hydride batteries designed for extremely high load may also be used in future motor cars to supply peak power for cranking and electrically driven accessories [195].

7.1.2.4. Nickel – Iron Batteries

The nickel – iron battery was developed in parallel to the nickel – cadmium battery at the beginning of the 20th century (see, e.g., [153, pp. 22]). It is based on the same electrolyte and the same (pocket-type) positive electrode. However, the active material of the negative electrode is iron.

Iron ions exist in two oxidation states as Fe^{2+} and Fe^{3+} ions. As a consequence two steps of electrode reaction are possible. The oxidation (discharge) of Fe to Fe^{2+} is described by:

$$Fe + 2\,OH^- \longrightarrow Fe(OH)_2 + 2\,e^-$$

with the standard electrode potential (in alkaline solution at pH 14) $U^{o,s} = -0.89$ V and the further oxidation of Fe^{2+} to Fe^{3+} occurs according to

$$Fe(OH)_2 + OH^- \longrightarrow Fe(OH)_3 + e^-$$

with the standard potential (in alkaline solution at pH 14) $U^{o,s} = -0.56$ V. The corresponding standard value of the hydrogen electrode

$$2\,H_2O + 2\,e^- \longleftrightarrow 2\,OH^- + H_2$$

is for comparison $U^{o,s}(H_2/H^+) = -0.828$ V. Thus the Fe/Fe^{2+} potential is 60 mV below the equilibrium potential of the hydrogen electrode,

Figure 98. Cross sections of cylindrical and prismatic nickel – metal hydride batteries (VARTA) [197]

Figure 99. Nickel – metal hydride battery; module for electric vehicle applications with battery management system and air cooling [198]

while the Fe^{2+}/Fe^{3+} potential is 268 mV positive compared to the H_2/H^+ equilibrium potential.

The normal charge/discharge cycle uses only the Fe/Fe^{2+} step. Fe^{3+} ions are only formed at extremely deep discharges or cell reversal. Thus under normal cycling condition the (simplified) cell reaction (see Section 7.1.2.1.2) is (left to right = discharge)

$$2\,NiOOH + Fe + H_2O \longleftrightarrow 2\,Ni(OH)_2 + Fe(OH)_2$$

and the open-circuit cell voltage $U^{o,s} = 1.38$ V, since the potential of the nickel hydroxide elec-

trode in alkaline solution is 0.49 V. The iron hydroxide forms together with OH^- ions complex compounds ($Fe(OH)_n^{2-n}$) of extremely low solubility. Thus, precipitation of the reaction product occurs within the pore system of the active material and the physical structure of the electrode remains almost stable (see Section 4.1.1.2). This situation is similar to that of the lead – acid battery and it is the main reason why this reaction can be reversed very often and that nickel – iron batteries can reach 4000 discharge/charge cycles.

At deep discharges, the final product is Fe_3O_4, that contains two Fe^{3+} ions and one Fe^{2+} ion:

$$8\,NiOOH + 3\,Fe + 4\,H_2O \longleftrightarrow 8\,Ni(OH)_2 + Fe_3O_4$$

The general situation of the nickel – iron battery is similar to that in Figure 78, the only difference is that the equilibrium potential of the negative electrode is 60 mV below the H_2/H^+-potential, and so hydrogen evolution occurs already at the open-circuit potential. This is a decisive disadvantage of the nickel – iron battery compared to the nickel – cadmium battery, and this all the more since the hydrogen overvoltage is low at the iron electrode. This means high gassing rates, a corresponding water loss, and high self-discharge rates that, at open circuit, discharge the battery completely within about three months.

Charging at too high rates has to be avoided, otherwise the increased polarization of the iron electrode causes such a high hydrogen evolution rate that the electrolyte is sprayed though the vent caps. To keep the battery fully charged in a standby application; a float current of about 0.5 A/100 Ah is required.

The discharge/charge characteristic shown in Figure 100 is similar to that of nickel – cadmium batteries. The slope of the discharge curve is steeper than that of nickel – cadmium batteries, since the iron electrode has a less stable discharge potential. At low temperatures a considerable decrease of the available capacity is observed, caused by the lowered reaction rates at the iron electrode.

Figure 100. Typical discharging – charging characteristic of a nickel – iron battery when charged at constant current. The positive electrode is capacity limiting so that the negative electrode is not deeply discharged.

Nickel – iron batteries were mainly used for traction applications due to their mechanical stability and the high cycle numbers that can be obtained. They were also employed for signal system since they can withstand abuse. In the western hemisphere, however, they completely lost their market in the 1970s to lead – acid or nickel – cadmium batteries. They are still in use in Eastern Europe, especially in the countries of the former Soviet Union.

The search for batteries, suited for electric vehicles caused a certain renaissance of this system, since it would be an inexpensive battery with high cycle capability. So, quite a number of projects were started to improve this battery system by a new design (cf., e.g., [175, p. 243 f]).

7.1.2.5. Nickel – Zinc Batteries

The nickel – zinc battery is a combination of the nickel electrode and a zinc electrode in an alkaline electrolyte. It is also closely related to the nickel – cadmium battery system. The oxidation reaction (discharge) of the zinc electrode is

$$Zn + 2\,OH^- \longrightarrow Zn(OH)_2 + 2\,e^-$$

with the standard electrode potential (in alkaline solution at pH 14) $U^{o,s} = -1.245$ V. Combination with the nickel hydroxide electrode gives the cell reaction

$$Zn + 2\,NiOOH + 2\,H_2O \longleftrightarrow 2\,Ni(OH)_2 + Zn(OH)_2$$

(left to right = discharge) with the cell voltage $U^o = -1.73$ V, since the potential of the nickel hydroxide electrode is 0.49 V (at pH 14). The

zinc electrode usually is made by pressing or rolling zinc oxide together with a binder and graphite as conducting aid. The result is the uncharged electrode that then is converted into a porous zinc material by charging (electrochemical reduction).

Zinc is an interesting electrode material. Its atomic mass of 63.4 g/mol is about half that of cadmium, and its more negative potential means a higher cell voltage and a correspondingly increased storage capability. The hydrogen overvoltage of zinc is high, and although the potential of a zinc electrode is 0.42 V negative compared to the hydrogen electrode, the hydrogen evolution rate is low as long as the zinc is not contaminated by foreign metals. Furthermore, for a technical product it is important that zinc is an inexpensive metal.

The problem of the zinc electrode is its solubility. This causes shape changing when discharging/charging cycles are repeated as indicated in Figure 4. Furthermore, zinc dendrites can be formed by precipitation of the dissolved material. They can penetrate the separator and form short circuits. To reduce this problem, various separators or combinations of separators have been tried (cf. Table 29.3 in [157]).

The design of a sealed nickel – zinc battery is possible. As in nickel – cadmium batteries, the negative electrode must have a "charge reserve" of uncharged material to avoid polarization that causes increased hydrogen evolution at the end of the charging process. The possible overcharging rate is limited in nickel – zinc batteries, on account of the required more dense separation between the electrodes to avoid the mentioned penetration by zinc dendrites. Figure 101 shows a typical charge/discharge curve.

Figure 101. Typical constant current charge – discharge curve of a sealed nickel – zinc battery

The general problem of nickel – zinc batteries is the limited number of possible cycles. At 100 % DOD, the capacity is reduced to 60 % within less than 300 cycles, but even at 30 % DOD only about 400 cycles are reached before the capacity drops below 60 %.

7.1.2.6. Silver Oxide – Zinc Batteries (cf. Section 6.1.3.2)

The silver oxide electrode as the positive one represents in combination with the zinc electrode the highest possible storage capability per weight and volume of the aqueous systems. Due to the existence of two positive oxidation states of silver (Ag^+ and Ag^{2+}) two discharge/charge reactions are possible. The discharge of divalent Ag^{2+} (its reduction) is described by

$$2\,AgO + H_2O + 2\,e^- \longrightarrow Ag_2O + 2\,OH^-$$

with the standard electrode potential (in alkaline solution at pH 14) $U^{o,s} = 0.599$ V; while the lower discharge plateau is given by the conversion of Ag^+ into Ag and the following reaction:

$$Ag_2O + H_2O + 2\,e^- \longrightarrow 2\,Ag + 2\,OH^-$$

with the standard electrode potential (in alkaline solution at pH 14) $U^{o,s} = 0.344$ V. In the battery, however, the discharge also of Ag^{2+} mainly occurs at the lower plateau, especially at increased load (cf. Fig. 102). When the electrode is recharged, complete conversion of Ag to the Ag^{2+} state is not reached.

The most common fabrication technique for silver oxide electrodes is by sintering silver powder at about 700 °C onto a substrate, usually expanded silver foil or silver-plated nickel. Subsequently, the sintered material is electrochemically converted to Ag_2O and AgO. Other methods start with the silver oxides that are pasted as a slurry onto the substrate. Subsequently, the slurry is sintered and simultaneously reduced to silver. Occasionally but mainly for primary batteries, chemically prepared AgO is pressed together with a binder onto the substrate and directly used as electrode.

Besides the high energy content, an advantage of silver-oxide electrodes is that the internal resistance of the electrode is reduced with progressing discharge, since metallic silver is formed by the discharge reaction. The result is a very flat discharge curve as shown in Figure 102.

Disadvantages of silver oxide electrodes are their high price and a certain solubility of silver oxides. Cellophane membranes are used as additional separators to hinder the migration of silver ions to the negative electrode. This affects the discharge performance at low temperatures. But even with such a multilayer separator, cycle live is limited on account of silver migration.

Combination with the zinc electrode gives the reaction equation

$$AgO + Zn + H_2O \longleftrightarrow Ag + Zn(OH)_2$$

with the open circuit voltage (upper plateau) $U^{o,s} = 1.84$ V. Combination of the silver-oxide electrode with the cadmium electrode results in

$$AgO + Cd + H_2O \longleftrightarrow Ag + Cd(OH)_2$$

with the open circuit voltage (upper plateau) $U^{o,s} = 1.41$ V. On account of the smaller cell voltage, the energy content of the silver – cadmium system is inferior to that of the silver – zinc system. But cycle performance is slightly better. As in nickel – cadmium batteries, the electrolyte does not participate in the cell reaction in both systems. Figure 102 shows typical discharge curves of silver-oxide batteries. Both systems are restricted to a niche market, mainly in medical or military applications.

Figure 102. Typical constant current discharge curves of silver – zinc and silver – cadmium batteries of comparable size

7.1.3. Rechargeable Batteries of Particular Design

The batteries treated in this section differ in their design from the batteries discussed in connection with Figure 1. In this "classical" design, the reacting substances are stored as "active material" in the electrodes. An already mentioned exception is the nickel – hydrogen battery (Section 7.1.2.2). Here the active material of the negative electrode, hydrogen, in its charged state is stored as a gas under high pressure not in the electrodes but in the container of each cell.

The battery systems, described in this section, store the active material outside the cells in separate tanks, or take it in the form of oxygen from the surrounding atmosphere. To some extent these batteries are hybrids of batteries and fuel cells. Their technical development was mainly initiated by the desire to overcome the limited storage capability of "classical" batteries. One mainspring of these efforts was the development of electric vehicles. Only batteries with increased storage capability would solve the problem of limited cruising range that opposes the acceptance of such vehicles.

In *chlorine – zinc* and *bromine – zinc batteries*, the active material is partially stored in exterior tanks, that in parallel supply all cells of the battery.

The *vanadium redox battery* stands for a whole family of batteries in which the active material is exclusively stored in the electrolyte. The electrode material does not participate in the electrochemical reactions but only acts as acceptor or donor of electrons. The capacity of such a battery is determined by the amount of electrolyte that is stored in the tank.

Air – zinc batteries take the active material of the positive electrode, oxygen, from the surrounding atmosphere. So the positive electrode does not contain active material, but only delivers electrons for the reduction of oxygen ($O_2 + 4\,e^- \longrightarrow 2\,O^{2-}$) (cf. Section 6.1.3.4).

Table 18 shows characteristic data of the mentioned battery systems.

7.1.3.1. The Chlorine – Zinc Battery

The chlorine – zinc battery was a predecessor of the bromine – zinc battery. It had been developed in the 1960s and 1970s for vehicle application (cf., e.g., [200], p. 302). It is based on the cell reaction

$$\text{Charging} \longleftrightarrow \text{Discharging}$$

$$Zn + Cl_2 \longleftrightarrow ZnCl_2$$

Table 18. Rechargeable battery systems of special design

	System	Equilibrium voltage, V/cell	Stored energy		
			Theory, Wh/kg	Practice, Wh/kg	Practice, Wh/L
1a	Zinc – chlorine	2.12	$\approx 500^a$	$\approx 110^b$	$\approx 130^b$
1b	Zinc – bromine	1.8	438	65 to 70	max. 70
3	Vanadium redox	1.6^c	$\approx 40^d$	20 – 30	20 – 40
2	Zinc – air	1.65^e	1320^f	$\approx 170^g$	≈ 200

[a] Assuming that chlorine is stored as $[Cl_2 \cdot 7\,H_2O]$. [b] Whole battery, including the thermos container. [c] When fully charged. At standard concentrations 1.26 V/cell. [d] When the vanadium solution alone is considered. [e] Open-circuit voltage in practice ≈ 1.4 V/cell. [f] Referred to pure zinc as negative electrode and to the charged state: Oxygen intake during discharge reduces the figure to 1211 Wh/kg. [g] Referred to the weight of the charged state.

The design uses a cell stack similar to that shown in Figure 103 for the bromine – zinc battery and two separate tanks to store the electrolyte, an aqueous solution of zinc chlorine. The positive electrodes are supplied in parallel by one tank, and the negative electrodes by the other tank. The electrolyte is pumped through the cell stack. Chlorine, that is generated during charging, is dissolved in water and forms the solid compound chlorine hydrate ($Cl_2 \cdot xH_2O$; $6 \leq x \leq 8$) at temperatures below 10 °C. This hydrate is stable at temperatures below 10 °C, accumulates at the bottom of the tank, and can so be stored. Therefore, adequate cooling of the tank is required during charging and storage in the charged state. When the battery is discharged, the electrolyte has to be warmed up and then releases the required chlorine.

Although the data shown in Table 18 are promising, the development was not continued due to technological problems.

7.1.3.2. The Bromine – Zinc Battery

The bromine – zinc system was pioneered by Exxon and Gould in the USA. The development was mainly continued by SEA in Austria. Prototypes of this battery system have been built. A great number of tests has been carried out in electric vehicles, and also stationary applications, like load leveling, have been included in the tests [201].

This battery uses zinc and bromine as active materials. The reactions are

	Charging	$\longleftrightarrow$	Discharging
Positive electrode	$Br_2 + 2\,e^-$	$\longleftrightarrow$	$2\,Br^-$
Negative electrode	Zn	$\longleftrightarrow$	$Zn^{2+} + 2\,e^-$
Cell reaction	$Br_2 + Zn$	$\longleftrightarrow$	$ZnBr_2$

During charging, zinc is precipitated as a solid metal, that is dissolved during discharge. At the positive electrode, the components of the reactions remain dissolved. Figure 103 shows the principle design of such a battery.

The cell stack shown in Figure 103 consists of only three cells. Actual batteries contain stacks of 50 or more cells. Except from the two end-plates, all electrodes are bipolar. They consist of an electron-conducting plate of carbonized plastic enframed by insulating plastic. On the positive electrode, a porous layer of carbon increases the surface to enhance the reaction rate of bromine. In the center of each cell, a microporous separator is positioned as used in lead – acid batteries (e.g., DARAMIC, a polyester nonwoven impregnated with phenol – resorcinol – formaldehyde resin) to suppress the direct contact between bromine and zinc as far as possible.

The electrolyte forms two circuits: one that flows in parallel through the compartments formed between negative electrodes and separators and through the tank on the left-hand side of Figure 103, and a second circuit along the positive electrodes and through the tank on the right-hand side of the figure.

On charging, zinc is deposited at the negative electrodes, and shape changing problems (c.f. Fig. 4) or the formation of zinc dendrites are not relevant, since the precipitation occurs from the fast streaming electrolyte. When the battery is discharged, the $ZnBr_2$ concentration is correspondingly increased.

At the positive electrode, bromine is formed during charging. The tendency of bromine to form complex compounds is supported by the addition of two complex-forming substances to the electrolyte: pyrrolidinium bromide and mor-

Figure 103. Bromine – zinc battery

pholinium bromide [202]. They form nonaqueous complexes with the generated Br_2 that is parted from the electrolyte as indicated in the tank on the right-hand side of Figure 103. When the battery is discharged, the bromine complex is added to the streaming electrolyte and bromine released.

7.1.3.3. The Vanadium Redox Battery

The vanadium redox battery uses also a cell stack of bipolar plates and two separate tanks that supply the compartments of the positive and the negative electrodes with electrolyte, similar to the design of Figure 103 (cf., e.g., Fig. 7.9 in [200]). An ion exchange membrane is used as separator in each cell.

This system makes use of the different states of oxidation that are characteristic for vanadium. The V^{5+}/V^{4+} equilibrium and the V^{3+}/V^{2+} equilibrium are used at the negative and positive electrode, respectively. The corresponding reactions are:

	Charging	$\longleftrightarrow$	Discharging
Positive electrode	$V^{5+} + e^-$	$\longleftrightarrow$	V^{4+}
Negative electrode	V^{2+}	$\longleftrightarrow$	$V^{3+} + e^-$
Cell reaction	$V^{5+} + V^{2+}$	$\longleftrightarrow$	$V^{4+} + V^{3+}$

The electrolyte is a mixture of 2 mol/L vanadium sulfate and 20 wt % sulfuric acid. Figure 104 shows charge discharge curves of a cell stack.

Figure 104. Charge – discharge curves of a vanadium redox battery. The cell stack consists of 17 cells; constant current of 100 Ah was applied for charging and discharging

A main advantage of such a redox system is that the electrode reactions do not involve solid phase changes or precipitation mechanisms. As a consequence, a large number of cycles can be reached, and deep discharges are not critical.

The most striking disadvantages of these systems are the comparatively low values of specific energy (Wh/kg) and energy density (Wh/L), shown in Table 18. They are caused by the low concentration of the reacting species on account of limited solubility. The specific power (W/kg) is limited for the same reason.

A further disadvantage is a certain transition of the positive vanadium ions from the compart-

ment of the positive electrode to that of the negative electrode, caused by migration (cf. Section 3.2). It results in gradual concentration increase in the compartments of the negative electrodes and requires occasional remix of the two electrolytes.

Shunt currents are unavoidable, caused by the required electrolytic connection between the individual cells of a stack. To keep these parasitic currents low, the connecting tubes must be small, but this simultaneously limits the high rate performance.

7.1.3.4. Rechargeable Air – Zinc Batteries

The air – zinc system is in widespread use as primary battery system, e.g., in the form of button cells for hearing aids (cf. Section 6.1.3.4).

The main advantages of the air – zinc system are the high values of specific energy and energy density shown in Table 18. This is partly due to the fact that the active material of the positive electrode is not contained in the battery when charged. Furthermore zinc is an element of low specific weight and offers a very negative equilibrium potential when used as an electrode.

The (simplified) electrode reactions are

	Charging	$\longleftrightarrow$	Discharging
Positive electrode	$1/2\,O_2 + H_2O$	$\longleftrightarrow$	$2\,OH^-$
Negative electrode	$Zn + 2\,OH^-$	$\longleftrightarrow$	$ZnO + H_2O$
Cell reaction	$Zn + 1/2\,O_2$	$\longleftrightarrow$	ZnO

Two problems arise in respect to recharging:

- The high solubility of zinc causes shape change as indicated in Figure 4.
- Intensive oxygen evolution that occurs at the positive electrode during recharge of the zinc electrode may damage the positive electrode.

A result of the first item is that in general zinc electrodes can stand only a very limited number of cycles.

One possibility to overcome this problem is to replace the used zinc electrodes after each discharge by new ones ("mechanical recharge"). The zinc oxide of the removed negative electrodes is regenerated in a central electrolysis unit that operates for a whole fleet of cars, equipped with such zinc – air batteries [204–206]. This procedure also solves the second problem, since the electrode is not recharged within the cell. Results of a larger fleet test in Bremen were disappointing [206], mainly for economical reasons connected to the regeneration of the zinc electrodes.

Another approach applies a small number (< 10) of recharges within the cell before the zinc electrode is replaced [207]. When the negative electrodes are recharged within the battery, auxiliary electrodes are used as positives. Extended fleet tests are planned.

7.2. Batteries with Nonaqueous Electrolyte

Alkaline metals, like lithium and sodium, are promising substances as negative electrodes for batteries of high storage capacity due to their negative electrode potential and low specific weight. They can, however, not be used together with aqueous electrolytes, because of their high reactivity to water. Alternatives are aprotic solvents that allow a certain conductivity, salt metals, or solid state electrolytes. The disadvantage of all these electrolytes is their comparatively low conductivity. In organic solvents this can be compensated by extremely thin and narrow spaced electrodes. Salt melts and solid state electrolytes require elevated or even high temperatures to achieve a sufficient high conductivity.

7.2.1. Rechargeable Lithium Batteries

The fundamental properties of lithium are shown in Section 6.2. As in primary batteries the layer that is caused by reactions between lithium and the electrolyte, called SEI (solid electrolyte interface) is formed at the electrode, prevents further attack at the metal, but allows the penetration of Li^+ ions. When the electrode is discharged, the protecting layer is destroyed, at least partially, and during a subsequent recharge some of the lithium is not precipitated as metal but contributes to further growth of the surface layer and is lost as capacity. Compared to primary batteries, the surface layer is less stable and normally a voltage delay as shown in Figure 28 is not observed with secondary batteries.

To compensate for the loss of capacity, rechargeable lithium batteries have to be equipped with a large excess of lithium to reach

a satisfactory number of cycles. But this implies the potential of hazards. If under anomalous operational conditions the temperature of the battery would reach the melting point of lithium (180 °C), the comparatively large amount of residual metal would react directly with the electrolyte and the battery might explode. For this reason, larger rechargeable batteries (cylindrical or prismatic) with metallic lithium electrodes and liquid electrolytes are only used for military applications, and are not available on the market.

7.2.1.1. Button or Coin Cells

Lithium as Negative Electrode. A great variety of small rechargeable button or coin cells exist, based on lithium as the negative electrode. These cells are mainly designed for memory backup, solar watches, pocket calculators, or similar applications. Most of them are 3 V systems, based on lithium alloys with aluminum as alloying additive as the negative and manganese dioxide or vanadium pentoxide as the positive electrode. But also polymers that can insert lithium, like polyaniline or polypyrrol, are used in the positive electrode.

The electrochemical reactions (when MnO_2 is used) correspond to those described in Section 6.2.1.1.2 for primary batteries, but here the subscript $(1-x)$ indicates that in such oxides the intercalation/de-intercalation mechanism can be repeated only within certain limits of the lithium content. Usually, in such layered oxides x is not allowed to exceed 0.5, otherwise the crystalline structure is changed (cf. Section 7.2.1.4.3).

	Charging	↔	Discharging
Positive electrode	$x\mathrm{Li}^+ + \mathrm{Li}_{(1-x)}\mathrm{MnO}_2 + x \cdot \mathrm{e}^-$	↔	LiMnO_2
Negative electrode	$x\mathrm{Li}$	↔	$x\mathrm{Li}^+ + x\mathrm{e}^-$
Cell reaction	$x\mathrm{Li}^+ + \mathrm{Li}_{(1-x)}\mathrm{MnO}_2$	↔	LiMnO_2

During discharge, in the positive electrode Mn^{4+} ions are reduced to Mn^{3+} and lithium ions are intercalated into the layered structure to compensate for the added negative charge. At the negative electrode, lithium is oxidized and dissolved.

During charging, the Li^+ ions are de-intercalated at the positive electrode, and a corresponding number of them are reduced and precipitated at the negative electrode.

The design of such button or coin cells corresponds to that shown in Figure 85. In general, the height of lithium button cells is small, particularly flat types occasionally are called coin cells. Figure 105 shows the cross-section of a typical example of the 3 V systems.

Figure 105. Cross-section of a button cell (Sanyo ML2430). CDMO means "composite dimensional manganese oxide" i.e., lithiated manganese dioxide Li_xMnO_2 $(0 \leq x \leq 1)$, produced by heat treatment (375 – 420 °C) of a mixture of LiOH and γ-MnO_2. Dimensions of the cell: diameter 24.5 mm; height 3.0 mm; weight 4.1 g

In this battery, the electrolyte is a mixture of ethylene carbonate (EC), butylene carbonate (BC), and dimethoxyethane (DME) to achieve desired features, like melting point and vapor pressure. The melting point must be low enough to provide sufficient conductance also at low temperatures, and the vapor pressure should not be too high to ensure proper sealing of the cell. Furthermore, the composition of the electrolyte greatly influences the stability of the protecting layer at the lithium surface. In the example of Figure 105, the conducting salt is $LiCF_3SO_3$. Often $LiAsF_6$ is applied for button cells, since As stabilizes the protecting layer at the negative electrode. A typical discharge curve is shown in Figure 106.

Figure 106. Discharge of the cell shown in Figure 105 by a resistor of 5.6 kΩ

7.2.1.2. Lithium Batteries with Polymer Electrolytes

Polymer electrolytes react less violently with metallic lithium electrodes and allow the direct combination without the danger of hazards. Such electrolytes are made of a polymer, like poly(ethylene oxide), with an incorporated lithium salt (e.g., $LiClO_4$, $LiPF_6$, $LiCF_3SO_3$) to achieve ionic conductivity. The disadvantage of these electrolytes is their low conductance that requires extremely thin electrolyte layers and mostly increased temperature to reach sufficient conductivity. Furthermore, the chemical stability of polyethylene oxide does only allow voltages up to about 3 V. For this reason, vanadium oxides (VO_x, e.g., V_2O_5 or V_6O_{13}) usually are employed in the positive electrode because the resulting cell voltage is in the range of 3 V. The electrode is formed as a thin layer mixed with carbon, rolled or pressed on a metal foil as current conductor. Figure 107 shows a corresponding arrangement of the electrodes and the polymer electrolyte. This combination reaches an overall thickness of only 100 µm:

Figure 107. Arrangement of the electrodes in a lithium polymer cell. The positive electrode (cathode) is a mixture of the polymer electrolyte with about 50 % of vanadium oxide (mainly the phases V_2O_3 or V_6O_{13}) and a small amount of carbon black (≈ 5 %) (3M/Hydro Quebec, [208])

The electrochemical reactions are (discharge from left to right):

Positive electrode	$y \cdot Li^+ + Li_{(1-y)}VO_x + y \cdot e^-$	$\leftrightarrow$	$LiVO_x$
Negative electrode	$y\,Li$	$\leftrightarrow$	$y \cdot Li^+ + y \cdot e^-$
Cell reaction	$y \cdot Li^+ + Li_{(1-y)}VO_x$	$\leftrightarrow$	$LiVO_x$

During discharge, lithium is dissolved at the negative electrode and absorbed by the positive one. During charging, lithium leaves the positive and is precipitated at the negative electrode. The electrode arrangement shown in Figure 107 can be used for various battery designs: especially flat and thin designs, spirally wound for cylindrical cells, but also for prismatic cells. A larger monoblock battery is shown as an example in Figure 108.

Figure 108. Prototype of a 24 V/80 Ah block battery (9 cells) designed for stationary applications, based on polymer electrolyte. (Dimensions: length 394 mm, width 176 mm, height 251 mm, weight 20 kg) [208]

This battery was developed to replace lead – acid batteries in stationary applications where the battery is continuously operated at elevated temperatures and the service life of a lead – acid battery is dramatically reduced. In such an application, positive utilization could be made of the disadvantage that sufficient conductivity of the polymer electrolyte is only reached at temperatures above 40 °C.

Figure 109. Discharge curve of the battery shown in Fig. 108 [208]. The voltage drop from about 3 to 2.4 V/cell is mainly caused by the positive electrode

The discharge curve of this battery is shown in Figure 109. It is typical for the VO_x cathode, and means that the voltage of a single cell drops from 3 V to 2.3 V during discharge. During the

discharge, the vanadium oxide passes through various structural phases that can be recognized by the different steps of the curve (cf. e.g., [209], p. 58).

The cycle number of such batteries is limited, mainly on account of the above mentioned growing layer at the lithium surface that consumes lithium and increases the internal resistance of the battery.

7.2.1.3. Batteries with Glassy Electrolytes

The possibility to design rechargeable all-solid state batteries, based on glassy electrolytes is described in [209], p. 199. Lithium ion conductive glasses reach conductivities in the range of 10^{-3} S/cm. Their general composition is $x\mathrm{LiI} \cdot y\mathrm{Li_2S} \cdot z\mathrm{SiS_2}$ where $\mathrm{SiS_2}$ can be replaced by $\mathrm{P_2S_5}$ or $\mathrm{B_2S_3}$ and instead of the lithium-iodine compound, LiBr or LiCl may be used.

Lithium is used as the negative electrode. Combination with $\mathrm{Li}_x\mathrm{TiS_2}$ and $\mathrm{Li}_x\mathrm{CoO_2}$ in the positive electrode leads to 3 V and 4 V batteries, respectively. Small coin cells with capacities in the range of 1 to 20 mAh reached more than 100 cycles at constant capacity and 100 % of coulombic efficiency.

7.2.1.4. Lithium-Ion Batteries

In lithium-ion batteries, intercalation and de-intercalation of lithium ions characterizes both electrodes. During discharge, the negative electrode releases $\mathrm{Li^+}$ ions, that are absorbed by the positive electrode, while these ions swing back, when the battery is charged.

In the negative electrode, nowadays mostly carbon intercalation compounds ($\mathrm{Li}_x\mathrm{C}_n$) are applied, only 1.5 V button cells employ certain oxides or sulfides as mentioned at the end of this section. Promising tin-based alloys as negative electrodes are still (2000) under development.

Specially pretreated carbons, based on graphite or coke, can absorb lithium ions or release these ions while a corresponding amount of electrical charges is drawn from or added to the carbon, respectively, according to

$$\mathrm{Li}_x\mathrm{C}_n \longleftrightarrow x\mathrm{Li^+} + \mathrm{C}_n + x \cdot \mathrm{e^-}$$

From left to right, this equation means discharging of the electrode (oxidation of carbon = de-intercalation of $\mathrm{Li^+}$ ions). The reversal, the insertion or intercalation of $\mathrm{Li^+}$ ions, means charging, i.e., reduction of the carbon by absorption of electrons. The negative charging simultaneously is compensated by the intercalation of a corresponding number of $\mathrm{Li^+}$ ions. Lithium does not form a real chemical compound with carbon, rather "intercalation" or "insertion" is largely based on electrostatic forces. (The reaction resembles the intake of $\mathrm{H^+}$ ions in the nickel hydroxide electrode, illustrated in Fig. 79).

Intercalation and de-intercalation at the negative electrode correspond to the precipitation and dissolution reactions of lithium electrodes, and the potential of such carbon electrodes is close to that of metallic lithium. Thus the combination with corresponding positive electrodes results in batteries of similar cell voltage. But the decisive difference is that the structure of the carbon host remains nearly unchanged when the electrode is charged or discharged. Only a slight volume increase is observed when the lithium ions are intercalated.

In the battery, such a carbon electrode is combined with a positive electrode of a metal oxide that also intercalates $\mathrm{Li^+}$ ions (mainly $\mathrm{Li}_x\mathrm{CoO_2}$, $\mathrm{Li}_x\mathrm{NiO_2}$, or $\mathrm{Li}_x\mathrm{Mn_2O_4}$). These positive electrodes intercalate the lithium when discharged, i.e., the lithium-filled material characterizes the discharged state. Then the $\mathrm{Li^+}$ ions compensate for a corresponding reduction of the metal ions ($\mathrm{Me^{4+}} + x \cdot \mathrm{e^-} \longrightarrow \mathrm{Me}^{(4-x)+}$). During charging, the $\mathrm{Li^+}$ ions are de-intercalated.

For $\mathrm{Mn_2O_4}$ (spinel) the reaction is

$$\mathrm{Li}_x\mathrm{Mn_2O_4} + x \cdot \mathrm{e^-} \longleftrightarrow \mathrm{Mn_2O_4} + x \cdot \mathrm{Li^+}$$

As in the carbon electrode, also in the positive electrode the host material remains (nearly) unchanged, and in the whole cell, only the $\mathrm{Li^+}$ ions swing between the positive and negative electrode, according to the cell reaction

$$|n\mathrm{C} + \mathrm{Li}_x\mathrm{Mn_2O_4} \longleftrightarrow \mathrm{Mn_2O_4} + \mathrm{Li}_x\mathrm{C}_n$$

This gave the battery the name "rocking chair battery" sometimes used. Figure 110 illustrates the system as a simple model.

The electrolyte is an organic (aprotic) solvent with a dissolved lithium salt that provides conductivity. On account of the comparatively low

Figure 110. Electrode reactions in rechargeable Li-C – Li-metal oxide batteries. In the positive electrode a layered structure of an oxide (here Mn_2O_4) absorbs Li^+ ions when discharged (left hand side), while in the negative electrode (on the right hand), carbon (here the layered structure of graphite, Li_xC_6) absorbs Li^+ ions when charged (from [210])

conductivity of organic electrolytes, the spacing between the electrodes has to be as small as possible. For this reason, in most lithium-ion batteries the thickness of the separator is about 25 µm and the thickness of the electrodes in the same order of magnitude. Only in low-rate button cells, these dimensions are larger (cf. Section 7.2.1.1). The arrangement of the electrodes is similar to that shown in Figure 107. Instead of the lithium electrode, a copper foil as current conductor with a layer of the carbon material forms the negative electrode, and the liquid organic electrolyte is soaked by a microporous separator. In most cases, the electrodes are wound up for cylindrical cells, corresponding to Figure 88.

Molybdenum Oxide, Niobium Oxide, or Titanium Oxide as Negative Electrode. Button cells, with MoO_2 $Nb_2O_5TiS_2$ as negative electrode materials that intercalate lithium, represent 1.5V systems. They were mainly designed for the direct substitution of nickel – cadmium or nickel – metal hydride batteries. The reaction equation for the negative electrode is, e.g., for MoO_2:

$$\begin{array}{ccc} \text{Charging} & \longleftrightarrow & \text{Discharging} \\ \text{LiMoO}_2 & \longleftrightarrow & \text{Li}_{(1-x)}\text{MoO}_2 + x \cdot \text{Li}^+ + \text{x} \cdot \text{e}^- \end{array}$$

At this negative electrode, the lithium-rich phase represents the charged state (the reduced state). Li^+ ions are de-intercalated during discharge, while the are intercalated during charging.

The potential of these electrodes is about 1 V positive compared to that of the metallic lithium electrode, and in combination with positive intercalation electrodes based on $LiMn_2O_4$, $LiCoO_2$, or $LiNiO_2$ a cell voltage of about 1.5 V results.

7.2.1.4.1. Lithium – Carbon Electrodes (Lithiated Carbons)

Carbon is available in a variety of crystallographic forms. For lithium intercalation,

graphite, but also other special modifications of carbon, are important (→ Carbon, Chap. 4.3.2.).

In such substances the carbon atoms form planes of hexagonal rings (C_6) that are arranged in layers with each second layer slightly shifted against the one below or above. The layers are only bound by van der Waals forces, and when the Li^+ ions are intercalated between these layers, the vertical distance between the layers is slightly increased (from 0.67 nm to about 0.75 nm).

Nongraphite carbons also consist of C_6 rings, but only small units of these rings exists, and these units are rotated with respect to each other. Such modifications are called "turbostratic carbons". They are denoted as *soft carbons* when they can be converted to a certain extent into graphite by annealing at high temperatures (up to 3000 °C). *Hard carbons* or *nongraphitizable carbons* are amorphous or glassy carbons that withstand such a conversion even at extremely high temperatures. In these materials the hexagonal fragments are fixed by cross-linking bonds that hinder the ordering into a graphitic structure. Hard carbons are mainly produced by pyrolysis of resins.

For graphite, the above general equation reads

$$Li_xC_6 \longleftrightarrow xLi^+ + C_6 + x \cdot e^-$$

where x can reach the value of 1, i.e., in maximum one Li^+ ion can be intercalated per C_6. The molar mass of LiC_6 is 79 g/mol, i.e., the storage capability of LiC_6 is $1 \cdot F = 28.6$ Ah per 79 g or 340 mAh/g. [Often this value is referred to the discharged electrode (C_6) with the molar mass 72.1 g/mol. Then the value is 372 mAh/g.] This is in the same order as the corresponding figure for the cadmium/cadmium hydroxide electrode. Charging and discharging of such a graphite electrode occurs at a potential that is only 0.1 to 0.2 V more positive than that of an electrode of metallic lithium. An example is shown in Figure 111. Thus, in regard to the charging – discharging characteristic, lithium – graphite electrodes can replace metallic lithium, but they cannot reach the specific energy of the metal electrode.

Fig. 111 shows a symptom that characterizes cells with lithiated carbon electrodes: the initial loss of lithium. The lithiated carbon is not stable, and the cell has to be assembled in the discharged state, i.e., with a lithium-free carbon electrode and the lithiated metal oxide (Li_xMO_2) in the positive electrode. During the first charge, lithium is intercalated in the carbon. Simultaneously, the surface layer (SEI), mentioned at the beginning of Section 7.2.1, is formed at the negative electrode by direct reaction between lithium and components of the electrolyte. During the subsequent discharge (and the following cycles), this amount of lithium cannot be recouped as capacity but remains in the layer. This share of the original lithium content is called "irreversible capacity" or "lost capacity" (C_{irr} in the upper part of Fig. 111).

The formation of such a protective film is of great importance. The protective layer must prevent co-intercalation of the solvent, but Li^+ ions must be able to pass. Especially in graphite, due to the comparatively weak van der Waals forces, solvated Li^+ ions [$Li_x(solvent)_y$] can be intercalated. On account of their large size, such solvated ions bend apart the graphite layers with causes a volume increase of more than 100 % and disintegration of the carbon electrode by exfoliation. The possibility to avoid such co-intercalation of the solvent depends to a large extent on the composition of the electrolyte, but also on the structure of the graphite.

Hard carbon or nongraphitizable carbon contains short layers of hexagonal carbon rings that are quite disordered, as indicated in Figure 112. As a result, both sides of the carbon layers are available for the adsorption of Li^+ ions. Furthermore, micropores may exist as an additional reservoir for Li^+ ions.

The increased number of positions for Li^+ ion adsorption results in a larger capacity than in the case of graphite-lithium intercalation compounds. In test cells, up to 700 mAh/g have been achieved, corresponding to the formula Li_2C_6. Fig. 113 shows the constant current-open circuit charge-discharge curve of the initial cycle. The irreversible capacity (C_{irr} in Fig. 111) is here denoted "loss". During the following cycles, the hysteresis between charge and discharge will be reduced, corresponding to the second cycle in Figure 111.

On account of nonequivalent sites of intercalation, the curves in Figure 113 do not show such a plateau slightly above the lithium potential, as it is observed in the case of graphite in Fig-

Figure 111. Constant-current charge/discharge curves of a graphite electrode referred to a metallic lithium electrode (Li/Li^+). Electrolyte: $LiN(SO_2CF_3)_2$/ethylene carbonate (EC)/dimethyl carbonate (DMC) (Fig. 7 on p. 392 of [213])

ure 111. Instead, charge and discharge occurs in a broad range of the potential. This means that a certain portion of the capacity can only be discharged at a lower cell voltage. Furthermore, at the end of the charging process, the electrode potential comes down very close to the potential of the metallic lithium electrode. This implies the danger of precipitation of metallic lithium which might form dendrites and so cause short circuits. In any case, such precipitated metallic lithium will react with the electrolyte and so get lost. On account of these limitations, in practical batteries, the aforementioned high capacity can only partly be utilized.

An advantage of hard carbons is that the cross-linking bonds do not allow the co-intercalation of solvents, and in general, volume expansion connected with Li^+ intake can be neglected.

Figure 112. Schematic model of the possibilities for lithium intercalation in hard carbon. The lines symbolize the carbon layers, the discs the intercalated Li^+ ions (part of Fig. 5.14 in [215], p. 113)

7.2.1.4.2. Negative Electrodes Based on Alloys

The application of lithium alloys in the negative electrode has been studied since the 1970s, because a great number of metals form lithium alloys that contain more lithium than can be inter-

calated in carbon negatives (a review is given in [211]). The main disadvantage of such alloys are large volume changes when lithium is absorbed (up to 100 %) that destroy the electrode. Another drawback is the low diffusion rate of the lithium ions at room temperature that limits the penetration depth of lithium. As a consequence, the size of the particles must be in order of manometers and they should be embedded in a host material in a way that allows volume increase.

To solve these problems, tin-based oxides (amorphous tin-based oxide, ATCO, or tin composite oxides, TCO) have been introduced by Fuji in 1994 [212]. They are mixtures of SnO, B_2O_3, $Sn_2P_2O_7$, Al_2O_3, and graphite and offer the possibility of negative electrodes with high capacity up to 650 mAh/g and also a certain cycle stability (cf., e.g., p. 406 in [213]). During charging the SnO obviously is reduced to fine Sn particles, that alloy up to 4.4 Li ions per Sn [214] and are embedded in an amorphous ductile surrounding.

A further method to create alloys of a sufficient small particle size is electroplating of corresponding mixtures. The cycle stability of such mixtures is much better than that of the pure substance. Thus, mixtures of Sn – SnSb or Sn – $SnAg_3$ – $SnAg_4$ are superior to Sn alone. The explanation is that the various phases react at different potential while the rest remains unchanged and so acts as a stable host ([211], p. 41).

On the whole, the described alloys are not yet (2000) stable enough to be used in commercial batteries but they are object of a worldwide intensive research.

7.2.1.4.3. Active Materials in the Positive Electrode (Cathode)

In the positive electrode, mainly three compounds and their variations are applied that have a high oxidation potential and a layered structure suitable for lithium intercalation: cobalt dioxide ($LiCoO_2$), nickel dioxide ($LiNiO_2$), and manganese dioxide (spinel) ($LiMn_2O_4$). Figure 114 shows a comparison of corresponding charge – discharge curves.

Figure 114 shows that also the positive electrode suffers a certain capacity loss between the first and the tenth cycle, the so-called "capacity fade". This parameter is strongly influenced by the composition of the compound but also by its structure that is determined by its preparation.

The extraction of lithium is limited, and the maximum of x usually should not exceed 0.5, when the oxide is described by $Li_{(1-x)}MO_2$ (M stands for Co, Ni, or Mn). When de-intercalation is continued beyond this limit by heavy overcharging, the structure of the material is irreversibly changed, and loss of capacity results.

Cobalt oxide was the first one used in commercial batteries. It has a stable layered structure. The mean discharge voltage against lithium is 3.8 V (Fig. 114 A). The main disadvantage of cobalt oxide is its high price. Furthermore, there are concerns about the toxicity of cobalt when run-down batteries are disposed of.

$LiNiO_2$ has a slightly lower discharge voltage than $LiCoO_2$ (mean value 3.52 V in Fig. 114 C) but a high capacity. It is more difficult to prepare and to maintain at an ideal layered structure, since nickel ions tend to occupy sites in the lithium layer and so disturb the structure. As Figure 114 indicates, a marked reduction of the capacity is observed between the first and the tenth discharge due to irreversible phase transitions during the first recharge. The main disadvantage of nickel dioxide is that Ni^{4+} oxides, formed by overcharging, are unstable and can cause hazardous reactions within the cell. For this reason, larger cells with nickel hydroxide in the positive electrode will be critical for safety reasons.

Substitution of cobalt for nickel, as in example B of Figure 114 ($LiCo_{0.5}Ni_{0.5}O_2$), can improve the situation.

Lithium manganese dioxide ($LiMnO_2$) is applied for primary batteries with lithium electrodes. However, the stability of the layered structure is not sufficient for a high cycle stability. But the lithium manganese spinel ($LiMn_2O_4$) is of great interest. Its structure corresponds to that of the mineral spinel $MgAl_2O_4$. $LiMn_2O_4$ is a relatively inexpensive material, offers a high electrode potential (mean discharge voltage 3.97 V in Fig. 114 D) and causes no safety risks as compared with nickel oxide and no environmental problems when the battery is disposed of. Disadvantages of the spinel are that at deep discharges (high Li^+ content) Mn^{2+} ions are formed that are dissolved and so lost from the electrode. Overcharging, on the other

Figure 113. Typical intermittent charge and discharge of a nongraphitizable carbon electrode at the initial cycle (doping = intercalation of Li^+ ions, undoping = de-intercalation). CCV: closed circuit voltage during constant-current charging and discharging. OCV: open circuit voltage.

Figure 114. Charge – discharge curves of various layered oxides versus lithium (button cells with lithium – aluminum alloys as negative electrodes). The solid lines represent the first cycle, the dashed ones the tenth cycle [215]

hand, causes the already mentioned undesired changes of the phase structure. Substitution of manganese, as shown in Figures 114 E and F ($LiCo_{0.3}Mn_{1.7}O_4$ and $LiNi_{0.4}Mn_{1.6}O_4$ respectively), provides the possibility to tailor the active material to the desired performance data and to overcome the mentioned difficulties.

7.2.1.4.4. Electrolytes

The liquid nonaqueous electrolytes are always a combination of an organic solvent and a lithium salt that effects the conductivity. One important condition is stability of the solvent in the wide voltage range of the 4 V system (the so-called

"voltage window"). Furthermore, the choice of the electrolyte is of great importance, since the protecting layer on the surface of the negative electrode results from reactions between lithium and components of the electrolyte.

Solvents, used in practical batteries, are, e.g., propylene carbonate (PC), ethylene carbonate (EC), or dimethyloxyethane (DME) (cf., e.g., Table 36.8 in [216] or Table 1, p. 460 in [213]). Often mixtures are applied to reach required features. The mostly used salt is $LiPF_6$. $LiAsF_6$is also applied, but has the disadvantage of environmental problems. Both salts are highly resistant to oxidation (large voltage window) and impart a comparatively high conductivity. But they tend to cause unwanted side reactions at higher temperatures. Especially developed for lithium-ion batteries were a number of salts with large molecular anions, like $Li[N(CF_3SO_2)_3]$ ("lithium imide") or $Li[C(SO_2CF_3)_3]$ (further examples and details cf. [213], p. 462). But the large molecular mass requires corresponding amounts of these salts to reach the ionic concentration, needed for sufficient conductivity, and this might not be possible due to limited solubility.

The electrolyte must be thoroughly freed from water, since even traces of H_2O would cause corrosion reactions with lithium and result in unwanted surface layers.

7.2.1.4.5. Separators

The separators in lithium-ion batteries are usually made of polyethylene or polypropylene films. Nonwoven material is only used in button cells designed for low load rates. Such a separator would not be suited in cells for higher loads, since there the thickness of the separator has to be in the range of 25 μm on account of the comparatively low conductivity of the organic electrolyte. Special films are required, characterized by an extremely fine pore system (≤ 0.1 μm) and able to withstand the mechanical forces of the cell manufacturing process, especially the winding for the production of cylindrical cells.

Such separators are known under various trade names, e.g., Cellgard and Setela. (cf. e.g., Table 1 on page 555 in [213]). The pore system is created either by filling fluids that later are extracted (wet process) or by overstretching the film (dry process).

Combination of layers of polypropylene and polyethylene are used to increase the safety of the battery. When the melting point of polyethylene (135 °C) is exceeded, the pores in this layer are closed, and the current flow is interrupted, while the polypropylene layers (*mp* 165 °C) are still stable. Thermal runaway is so avoided.

7.2.1.4.6. Lithium-Ion Polymer Batteries

Particular interest exists for lithium-ion batteries with polymer electrolyte, since such batteries could be manufactured in any shape, they would not have leakage problems and could easily be miniaturized. Credit cards or similar applications afford such a battery design. Disadvantages of polymer electrolytes are their low conductivity, and that an additional resistance may be caused by contact problems between the surface of the electrodes and the polymer (wetting problems).

A solution of these problems is offered by "gel electrolytes" or "gelionic electrolytes". They can be produced in two ways: immobilization of the liquid electrolyte by adding a soluble polymer or by filling a porous matrix with the liquid electrolyte. An example for the latter is the "Bellcore" process that has been licensed to a number of manufacturers (cf., e.g., Fig. 10.19 on p. 235 in [209]). It employs carbon in the negative and $LiMn_2O_4$ in the positive electrode. Both electrode films are rolled with a plastic layer on top of each, which later is filled with the electrolyte. Then both are combined with the separator between them. Subsequently the plasticizer is extracted from the plastic layers, and so a pore system created within them. Then the electrode group is filled with electrolyte. Thus, the electrolyte is not only soaked into the plastic layers and the separator, but it also gets in intimate contact with the electrode surface.

7.2.1.4.7. Practical Batteries

Since Sony introduced the first lithium-ion battery into the market in 1991, an exciting growth has occurred of the market share of this battery system. The first one was a cylindrical cell

(Sony 18650), based on nongraphitizable carbon in the negative and $LiCoO_2$ in the positive electrode. The battery reached the specific energy of 120 Wh/kg and the energy density of 300 Wh/L. A typical discharge curve is shown in Figure 115.

Figure 115. Discharge of a rechargeable lithium-ion cell (Sony 18650)

The cycle behavior of this cell is shown in Figure 116. Depending on the charging/discharging conditions, more than 2000 cycles have been attained [217].

Figure 116. Cycle performance of a cylindrical lithium-ion cell (Sony 18650). Charge: constant current 1 A; constant voltage 4.2 V; Discharge: constant current 1 A, end of discharge voltage 2.7 V

The $LiCoO_2$ used in the Sony 18650 cell contains a small amount of Li_2CO_3 which is added when $LiCoO_2$ is synthesized. When the cell is charged to a voltage higher than 4.8 V, the Li_2CO_3 is decomposed and the resulting CO_2 gas increases the internal pressure. Then, a concave aluminum disk at the top of the cell is pushed upwards, as shown in Figure 10, which interrupts the current flow between the cover and the electrodes. Hazards by overheating are so avoided.

Today (2000) a great variety of lithium-ion batteries is offered by different manufacturers. Usually they are smaller sizes cylindrical cells or button cells, since most applications are portable devices, such as cellular phones, notebooks, and camcorders.

The strong efforts to develop advanced batteries for electric vehicles, sponsored, e.g., by United Stated Advanced Battery Systems Consortium (USABC), initiated the development of large batteries for traction applications. Figure 117 shows such a battery.

Figure 117. Prototype of a lithium-ion cell for electric vehicle application
Dimensions: width 30 mm; height 153 mm; length 210 mm; specific energy (at 25 W/kg continuously): 115 Wh/kg; energy density (C_5) 270 Wh/L (VARTA R&D Center, Kelkheim [218])

On account of the high energy content, batteries of such cells can only be operated in connection with battery-management systems that control each cell.

7.2.2. High-Temperature Batteries

The high-temperature batteries make use of a salt melt or of β-alumina, a solid electrolyte that gains its conductance by the mobility of sodium ions. In both cases, temperatures between 300 and 400 °C are required to reach sufficient conductivity of the electrolyte.

The high operating temperature of these batteries is a drawback, since it requires expensive thermal insulation and temperature management. But the performance data are attractive as shown in Table 19.

Table 19. Rechargeable battery systems that operate at high temperatures

	System	Equil. voltage, V/cell	Stored energy		
			Theory, Wh/kg	Practice, Wh/kg	Wh/L
1a	Iron sulfide – lithium [a,e]	1.35	459	90 – 110	max. 200
1b	Iron disulfide – lithium [b,e]	1.73	490	150 – 170 [c]	max. 350 [c]
2	Sulfur – sodium [f]	2.1	795	90 – 120 [d]	max. 180 [d]
3	Nickel chloride – sodium (ZEBRA) [f]	2.6	719	80 – 100 [d]	max. 160 [d]

[a] Li(Al) – FeS. [b] Li(Al) – FeS_2 when the upper plateau is only used (Fig. 118). [c] Bipolar version. [d] Figures concern the whole battery including thermal insulation. [e] Operating temperature ≈ 450 °C. [f] Operating temperature temperature ≈ 300 °C.

The development of these three systems has greatly been favored by the search for advanced batteries to power electric vehicles. The low specific energy of lead-acid batteries limits the range of such vehicles to about 80 km, and this range can be more than doubled by a high temperature battery of the same weight, as a comparison between Tables 19 and 13 shows.

7.2.2.1. Iron Sulfide – Lithium Batteries

The development of this system started in 1968 and subsequently has been continued to an essential part at the Argonne National Laboratory. Originally, lithium and sulfur were tested as electrode materials. Later, lithium – aluminum alloys and metal sulfides have been used as active material in the negative and positive electrodes, respectively. A molten eutectic mixture of lithium chloride and potassium chloride is used as the electrolyte in the battery that is operated at about 450 °C.

Iron and sulfur form two compounds: iron sulfide (FeS) and iron disulfide (FeS_2, pyrite). In both iron is in the divalent state (Fe^{2+}). Iron disulfide belongs to the group of polysulfides (MeS_x), containing S_x^{2-} anions.

If iron sulfide is used as the positive electrode and a lithium – aluminum alloy as negative electrode, reduction of iron (II) and oxidation of lithium results in the overall reaction

$$FeS + 2\,Li(Al) \longleftrightarrow Li_2S + Fe + 2\,Al$$

Proceeding from left to right means discharge, and the electrode reactions are:

$$\text{Positive electrode } FeS + 2\,e^- \longrightarrow Fe + S^{2-}$$

$$\text{Negative electrode } 2\,Li + S^{2-} \longrightarrow Li_2S + 2\,e^-$$

When the battery is charged, both reactions are reversed. The open-circuit voltage of the cell reaction is $U^{o,s} = 1.64$ V.

Compared to FeS, the energy content of pyrite is slightly higher. In combination with a lithium – aluminum alloy, the (simplified) cell reaction results:

$$FeS_2 + 2\,Li(Al) \longleftrightarrow +2\,Li_2FeS_2 + 2\,Al$$

with the open circuit cell voltage $U^{o,s} = 1.73$ V. This reaction causes the "upper plateau" discharge curve in Figure 118. The formed intermediate phase Li_2FeS_2 can further be discharged according to

$$Li_2FeS_2 + 2\,Li(Al) \longleftrightarrow 2\,Li_2S + Fe + 2\,Al$$

This second step causes the lower plateau in Figure 118. But when this reaction occurs, FeS_2 can only be recouped by charging voltages above 2.5 V/cell. For this reason, the discharge of FeS_2 is usually restricted to the upper plateau (see [220, p. 464]).

Figure 118. Constant-current discharge curves of iron sulfide – lithium batteries

Iron sulfide – lithium batteries have been designed as prismatic cells with an appearance similar to the nickel – cadmium battery shown

in Figure 86 (c.f. Fig. 39.1 in [199]). Felts of boron nitride or pressed powder sheets of magnesium oxide have been used as separators. The latter contain a limited amount of electrolyte, so that free liquid electrolyte is not present in the cell. The current collectors are made of steel for the negative electrode and also for the positive one, when FeS is used. In the FeS_2 battery molybdenum usually is applied as current conductor in the negative and the positive electrode. A ceramic seal is required for the post, usually the positive one, while the negative electrode is connected to the container.

The bipolar version represents the most compact design due to the minimized path length for the current. The principle is shown in Figure 119. Lithium – iron sulfide batteries in the bipolar design (cf. Fig. 39.11 in [199]) gave the excellent performance data shown in row 1 b in Table 19.

Figure 119. Bipolar battery design consisting of four cells. In the case of the iron sulfide – lithium battery, the separator is pressed MgO filled with the (starved) electrolyte, and the bipolar plates are molybdenum sheets. Special ceramics have been developed to achieve safe sealing of the bipolar plates and so prevent electronic or ionic contacts between the cells.

Despite enormous efforts by Argonne National Laboratories and a number of battery manufacturers for more than thirty years, and despite its excellent performance data, the iron sulfide – lithium battery did not yet reach a position in the market. Main problems are corrosion and high manufacturing and material costs.

7.2.2.2. Sodium – Sulfur Batteries

The start of an intense technical development of the sulfur – sodium battery system began at the Ford Motor Company's laboratory [219] and was strengthened as a reaction to the first oil crises in 1973. The idea was to make electric road vehicles more competitive by an increased driving range (for a detailed description see [220]). Research and development were continued by a number of groups, so on a large scale by Chloride in England and BBC (later ABB) in Germany [221]. The batteries consisted of a great number of identical cells in parallel strings (similar to the battery shown in Fig. 125). Practical experiments with a larger fleet of various vehicles were conducted for a number of years. However, Chloride and ABB discontinued their development in 1996. At present (2000), the system is further developed and tested for stationary applications in Japan by NGK Insulators Ltd. [222].

Sulfur – sodium and nickel chloride – sodium batteries are closely related to each other. Both employ β-alumina that simultaneously acts as the solid electrolyte and the separator. β-Alumina is a compound composed of aluminum oxide and sodium oxide. Their molar ratios ($Na_2O : Al_2O_3$) can vary between 1 : 1 and 1 : 11 (→ Aluminum Oxide, Chap. 1.6.). β-Alumina has the appearance of unglazed ceramic. At temperatures of about 300 °C, a sufficient high mobility of the sodium ions is achieved. Figure 120 shows the construction of a cell of the sodium – sulfur battery. Such cells manufactured by ABB had a capacity of 40 Ah per cell. Chloride used small cells of only 10 Ah per cell and a correspondingly higher number of cells per battery.

Figure 120. Cell of a sulfur – sodium battery (ABB)

The separator of β-alumina that simultaneously is the electrolyte, forms a cylindrical cup. Within this cup, the sodium is located. It is the active material of the negative electrode, that is molten at the operating temperature. The space between the β-alumina cup and the outer cell case of aluminum or mild steel is filled with sulfur, which is also liquid at this temperature. Sulfur is mixed with graphite felt, since sulfur itself does not conduct the electric current. In the β-alumina cup, a cup of stainless steel is inserted with a small hole in the bottom. This "safety inset" prevents an uncontrollable thermal situation in the case that cracks were formed in the ceramic separator and sodium and sulfur would get into direct contact (internal short-circuit). The small opening in the bottom of the safety inset limits the flow of sodium. Thus the rate of the reaction and also the heat generation are limited, and the diameter of the opening in the safety inset is designed so small that safe heat dissipation is possible also in the case of the internal short-circuit. The safety inset simultaneously acts as current collector.

When the cell is discharged, sodium ions migrate through the β-alumina wall and form NaS_x compounds with increasing sulfur content according to the sequence of reactions given in Table 20.

Table 20. Sequence of discharge – charge reactions of the sodium – sulfur cell

Charge $\longleftrightarrow$ Discharge	$U^{\circ}*$
$2\,Na + 5\,S \longleftrightarrow Na_2S_5$	2.08 V
$2\,Na + 4\,Na_2S_5 \longleftrightarrow 5\,Na_2S_4$	1.97 V
$2\,Na + 3\,Na_2S_4 \longleftrightarrow 4\,Na_2S_3$	1.81 V

$*$ U° values at 300 °C.

According to this sequence, the equilibrium cell voltage is slightly reduced with progressing discharge. Typical charge – discharge curves are shown in Figure 121. Since there are no secondary reactions, a steep increase of the charging voltage indicates that the state of complete recharge is reached. Thus, in a series-connected string of cells, the voltage across the cell that first reaches full charge may attain very high values, and damage of the β-alumina may be the consequence. As a remedy, a sulfur – sodium battery always contains a number of paralleled strings of cells with cross connections.

With rising temperature, the voltage difference between charging and discharging decreases, i.e., the efficiency of the battery is improved. Since there are no secondary reactions, the coulomb efficiency (charged/discharged Ah) is 100 %, and only the voltage gap between charging and discharging causes that the energy-storage efficiency (charged/discharged Wh) is lower than 100 %. Since this gap is reduced with rising temperature, the Wh efficiency is increased with temperature and reaches values up to 90 %.

Figure 121. Charge/discharge curves of a sulfur – sodium battery at various temperatures [223]

The design of a complete battery including the thermal insulation is similar to that shown in Figure 125 for nickel chloride – sodium batteries.

The main problems of sulfur – sodium batteries are:

- Internal short circuits, caused by overcharging or hot spots (sodium dendrites). The failed cell attains a high internal resistance so that the whole string is blocked.
- Mechanical defects (separator or cell seal) caused by thermal cycles (too rapid heating or cooling).

7.2.2.3. Nickel Chloride – Sodium (ZEBRA) Batteries

The nickel chloride – sodium battery also uses sodium for the negative electrode and β-alumina as separator and solid electrolyte. Nickel chloride ($NiCl_2$) is used as active material for the positive electrode that is reduced to the metal when discharged. Both nickel chloride and nickel metal remain in the solid state despite the high

operating temperatures of the battery. For this reason, these batteries must use an intermediate electrolyte which is a molten salt, namely sodium aluminum chloride ($NaAlCl_4$). This intermediate electrolyte involves some benefits, described below.

The development of this battery system was started under the name "ZEBRA battery" by the Anglo African Oil Company in South Africa (code for the project was the abbreviation **ZE**olites applied to **B**attery **R**esearch **A**frica [220, p. 380]) and continued in cooperation with AEG Anglo Batteries GmbH, Ltd. in Germany and England. Although a large number of such batteries were being tested in vehicles and proved quite successful [224], it was decided to discontinue the development at the end of 1998.

Figure 122. Vertical cross section of a nickel chloride – sodium cell

In principle, an iron chloride – sodium electrode can also be used as the positive electrode and has also been tested as well as mixtures of iron and nickel. Iron would be attractive as a less expensive material offering an only slightly reduced cell voltage ($U^o = 2.35$ V/cell). But iron proved to have a number of drawbacks, and the later development concentrated on positive nickel electrodes (cf. [220, p. 387]).

The construction of a nickel chloride – sodium cell is shown in Figure 122. It looks similar to a sodium – sulfur cell, but here sodium fills the volume between the β-alumina cup and the cell container, while the positive electrode, the $Ni/NiCl_2$ electrode, is located in the center. Molten $NaAlCl_4$ forms the ionic contact between the solid positive electrode and the solid electrolyte.

The nickel electrode is produced by sintering a fine powder of nickel tetracarbonyl together with sodium chloride and aluminum. The result is a structure of high porosity.

The intermediate electrolyte ($NaAlCl_4$) involves some benefits. When the cell is overcharged, the intermediate electrolyte reacts with the active material of the positive electrode according to the reaction:

$$2\,NaAlCl_4 + Ni \longrightarrow 2\,Na + 2\,AlCl_3 + NiCl_2$$

which has the equilibrium cell voltage $U^o = 3.05$ V. On account of this high equilibrium voltage, this reaction does not occur during the normal charging process. If the battery has been overcharged, this reaction is reversed during the subsequent discharge.

When the battery is overdischarged, the intermediate electrolyte reacts with sodium according to

$$NaAlCl_4 + 3\,Na \longrightarrow Al + 4\,NaCl$$

with the equilibrium cell voltage $U^o = 1.58$ V. This reaction is reversed when the battery is recharged. Thus, the intermediate electrolyte allows overcharging and overdischarging to a certain extent. Furthermore, the molten $NaAlCl_4$ bridges the cell in the case of failure. A string of cells is so kept workable despite of failed cells, although at a reduced string voltage.

Figure 123. Horizontal cross section of a nickel chloride – sodium cell [225]

In the latest design, a cloverleaf shaped β-alumina cup was used instead of the simple cylinder, and a prismatic cell container instead a cylindrical one, as the horizontal cross-section in Figure 123 shows. (In Fig. 125 the older cylindrical cell containers are shown). The surface of the separator was significantly increased by this

improved design, and the prismatic container makes better use of the battery volume.

The electrochemical reactions are:

		Charge $\longleftrightarrow$ Discharge
Positive electrode	$NiCl_2 + 2\,Na^+ + 2\,e^-$	$\longleftrightarrow Ni + 2\,NaCl$
Negative electrode	$2\,Na$	$\longleftrightarrow 2\,Na^+ + 2\,e^-$
Cell reaction	$NiCl_2 + 2\,Na$	$\longleftrightarrow Ni + 2\,NaCl$

with the equilibrium cell voltage $U^{o,s} = 2.58$ V. Figure 124 shows typical discharging and charging curves. The decreasing voltage near the end of discharge indicate the increasing internal resistance.

Figure 124. Typical voltage curves for the discharge of a ZEBRA battery at the 4-h and 2-h rate, and recharge at the 4-h rate. Charging and discharging occurs with constant current.

The equilibrium potentials of the overcharge and overdischarge reactions are inserted in Figure 124. They show that the cell voltage will not significantly exceed the normal range, when the cell is overcharged or deep discharged.

Figure 125 shows a complete battery and its construction. The battery consists of a great number of cells, which stand upright side by side. The cells have metallic containers and are insulated from each other by foils of mica. The cell assembly is encapsulated by a specially developed container of excellent thermal insulation, including vacuum. For temperature control, cool air can be blown through the interior. Electrical heating elements are inserted for heating up the battery to the minimum value of 200 °C where the charging process can be started. These heating elements are also used to keep the battery hot, if it is not used for a certain period of time.

8. Battery Standards

8.1. General

A standard is an item considered by general consent as a basis of comparison, if it is in compliance with the requirements of relevant directives and guidelines. A technical standard may relate, e.g., to shape and dimensions. In the case of a battery, the standard will also refer to the electrochemical system employed, its electrical performance characteristics, its terminal arrangements, and to its unambiguous identification, derived by a unique nomenclature system.

A technical standard is expected to

- foster international trade, and/or
- protect the consumer, and/or
- assure interfacing, interchangeability compatibility or interworking, and/or
- improve safety and health, and/or
- protect the environment.

8.2. National Standards

Before International Standards became available, National Standards for battery systems were established by National Committees, working independently from each other. National Standards are for instance ANSI (American National Standards Institute), BSI (British Standards Institute), DIN (German Industrial Standard), JIS (Japanese Industrial Standard), etc.

With the growth of international trade there was a need to coordinate the activities of these National Committees. Within the European Community this coordination is done by CENELEC [227]. CENELEC works closely together with the IEC and is expected to become one day the only European Standards Organization, superseding all National Committees of the European Community.

During the last two decades quite a few National Committees have started to harmonize their Standards with IEC Standards, especially for primary batteries. In the meantime the majority of National Committees have been fully harmonized. Nevertheless, some national and/or regional standards are still in existence, and will continue to be part of their country's legislation.

Figure 125. Construction of a nickel chloride – sodium battery (from [226]) In the latest design, the cylindrical cell containers are substituted by prismatic ones (see Fig. 123). The energy content of such a battery is about 30 kWh.
a) Terminal; b) External container wall; c) Thermal insulation (vacuum); d) Internal container wall; e) Heating element; f) Electrical insulation; g) Cell; h) Electrical insulation between cells

8.3. International Standards

8.3.1. Technical Committees and how they operate

In consequence of the growing needs to coordinate the activities of National Committees, two Technical Committees on batteries were set up under the auspices of the IEC [228]. The first IEC Technical Committee on batteries that was established in 1931 was Technical Committee No. 21 (TC21). It focusses solely on lead – acid batteries. In 1965 a Sub-Committee SC21A was added, dealing with "*Secondary Cells and Batteries, containing alkaline (e.g. Nickel-Cadmium batteries) or other non acid electrolytes (e.g. Lithium-Ion batteries)*". In 1949 a second IEC Technical Committee was set up, dealing solely with primary batteries, i.e., Technical Committee No. 35 (TC35).

Meanwhile more than 100 IEC Technical Committees and Sub-Committees are in existence, covering the whole field of electrotechnical components, devices, and machinery. Each Technical Committee and Sub-Committee is guided by a Chairman and a Secretary, being elected according to the "Procedures" of the IEC Directives Part 1 [229]. These procedures also clarify the rights and duties of National Committees, Chairman, and Secretary when carrying out IEC work. National Committees, Chairman, and Secretary are in close contact with each other, and with the Central Office of the IEC, which provides technical and administrative services to the Technical Committees.

The IEC Technical Committees are operated by consultation and discussion; the participants being experts appointed by their National Standards Organization. When a point of agreement is confirmed by a formal postal vote, it is incorporated into the IEC Standard.

A new standard starts always with a "New Work Proposal" that may be submitted by any National Committee or by the Secretary himself. It depends on National Committees whether or not this New Work Proposal is approved and whether or not it is finally processed to an International Standard. The standardization procedure takes in general three to four years.

At present, well above 25 countries are participating in the work of Technical Committees No. 21 and No. 35. IEC Standards are voluntary standards, unless they are part of a country's legislation.

In order to progress the IEC work, the experts of a Technical Committee have to meet regularly. The meeting may be a Working Group meeting or a meeting of the Technical Committee, which has the authority to take decisions on new standards and future work (strategic policy). The meeting place is determined by the inviting National Committee and may be at any place of the world. This means travel expenses for the experts, which are not covered by their National Committee but by the company the expert is associated with. Experts of TC21, SC21A

and TC35, are prevailingly associated with battery companies.

Part 2 of the IEC Directives cover the "Methodology for the development of International Standards" [230], its principles and requirements to be observed by Technical Committees and their subsidiary bodies. Part 2 is considered to be the most important part of the IEC Directives, since it has a direct impact on the quality of the IEC Standard. In contrast to Part 1 of the Directives, the contents of Part 2 and its application to standards is not enforced by an official IEC body. This is left to the individual Technical Committee, which is required to comply with the principles and rulings of the Directives, Part 2. In practice, however, international consensus is given the first priority, which is not always based on the requirements of the IEC Directives, Part 2.

Part 3 of the IEC Directives contains the "Rules for the structure and drafting of International Standards" [231].

When voting is required, each National Committee has one vote only, independent of the size of the population it represents.

8.3.2. TC21, SC21A , TC35, and Their Standards

The IEC Standards on Batteries are listed in Section 8.4 ((Annex 1)). Since the Standards of TC21, SC21A, and TC35 were set up at different times and by different experts, their contents differ in structure. The contents may, however, in general be allocated to following subjects

1) Scope
2) Normative references
3) Definitions
4) Requirements
5) Designation and marking of cells and batteries
6) Dimensions
7) Performance testing
8) Test conditions
9) Specification tables and sheets
10) Product relevant annexes (normative and informative)

The contents of Standards on Battery Safety may be allocated to following subjects

1) Scope
2) Normative references
3) Definitions
4) Requirements for safety
5) Instruction for use
6) Testing and requirements
   Intended use
   Reasonably foreseeable misuse
7) Safety precautions during handling
8) Safety precautions during packaging, storage, transportation, and disposal
9) Marking
10) Annexes (normative and informative)

IEC standards are under constant review, thus ensuring that their contents reflect current technology. When using the IEC Standard it must be ensured that its latest edition is consulted.

8.3.3. TC21, SC21A, and TC35: Harmonization of Standards

A comparison of the standards of TC21, SC21A, and TC35 has revealed that, due to the independent work of the committees, their standards have arrived at different results on some similar subjects. In this respect two areas were identified:

1) Definitions as presented in the relevant IEV vocabularies
2) Nomenclature system for batteries as presented in the relevant standards

Consequently two joint working groups (experts from both Technical Committees) were set up in recent years with the task to harmonize the standards and to resolve unnecessary differences.

8.3.3.1. IEC Vocabulary on Batteries

The harmonizing work was based on existing IEC vocabularies, i.e.,

1) IEV 60050-481: Primary Cells and Batteries [228]
2) IEV 60050-486: Secondary Cells and Batteries [228]

The task was to amalgamate both vocabularies. Since the Joint Working Group could not resolve the discrepancies the project was transferred to IEC Technical Committee No. 1, which has specialized on IEC definitions.

8.3.3.2. Harmonization of the Nomenclature Systems

Three IEC nomenclature systems plus variants are presently in use. They were developed by TC21, SC21A, and TC35 at a time when no IEC Directives were available. Consequently none of them was developed in compliance with the IEC Directives, Part 2, section 7, annex E: Designation of Standardized Items [230].

The task of the joint working group was therefore to harmonize existing nomenclature systems and/or to derive a completely new unique and logical nomenclature system for all batteries, being in compliance with the IEC Directives, Part 2 and its principles, and being suitable for data processing. A proposal of this kind [232] that initially found favorable support finally failed. An agreement on a different proposal [233] could not be reached either.

As a result the task was abandoned. This outcome is regrettable, not only for the consumers for reasons given below (cf. Section 8.5 and 8.6) but also in regard to the technical professionalism of this International Standard.

8.3.3.3. Designation of Batteries, Present Status

Since batteries have been available on the market, consumers have been confronted with battery designations of different origin, i.e.:

1) Manufacturer's designation
2) Designations according to National Standards
3) Designations according to IEC Standards

and mixtures thereof.

The present status is illustrated in Table 21. Table 21 lists 15 batteries arbitrarily picked from a range of button batteries, cylindrical batteries, and prismatic batteries of different primary and secondary electrochemical systems. Each row contains designations of batteries being identical in dimensions and electrochemical system. All batteries belong to the group of portable batteries.

The left part of Table 21 lists the battery type, its dimensions, followed by IEC codes, i.e., nominal voltage/system letter and the battery's IEC designation.

The right part of Table 21, as given by columns 1 – 6 contain manufacturers designations. The designations listed are used by well-known international battery companies. Some of them have started to use IEC designations instead, especially in Japan.

The confusing number of different designations for batteries, being identical in size and system, speaks for itself. A more detailed discussion of the contents of Table 21 is given in Section 8.5 ((Annex 2)).

Former ANSI designations are still in use, although having been no more valid for a long time. The more popular ones of these designations are listed in Table 22. Table 22 also contains equivalent IEC size designations. Originally, the former ANSI designations addressed carbon-zinc batteries with different dimensions, as given in Table 22. Today former ANSI codes are still in use as size codes, e.g., in combination with IEC system- and shape-letters like CR1/2AA.

8.3.3.4. IEC Nomenclature Systems for Batteries

In general, presently valid IEC nomenclature systems address two aspects of a battery:

1) Physical aspects such as shape, dimensions, and terminal arrangements
2) Electrical aspects such as voltage, electrochemical system, capacity, load capability and type of electrode (pocket plates, sintered plates etc.)

The information given in the designation, has in general the following sequence:

1) Voltage: Either in clear or by code, i.e., number of cells connected in series in combination with a system letter, to which the system's nominal voltage is allocated.
2) The system letter(s) denotes the electrochemical system in the sequence (see Section 8.7 ((Annex 4)) for details): positive electrode – electrolyte – negative electrode

Table 21. Designations of Batteries being identical in Dimensions∗ and Electrochemical System

No	Battery type	Dimensions, mm			IEC	Battery designations as used by different international manufacturers					
		Length	Width or Height diameter	Norm. voltage/syst. letter(s)	Designation	1	2	3	4	5	6

* Within given tolerances

3) Shape letter: B for button batteries, R four round batteries (including button and cylindrical shape), P for prismatic and non-round batteries.
4) Size: Either by code or by dimensions. Since the battery volume correlates with its capacity, reference is sometimes made to the capacity instead.
5) Load capability: L, M, H and X for low, medium, high and very high rate for nickel-cadmium batteries. For primary batteries no load-classification is available.
6) Contact and performance variants.

It would be beyond the scope of this article to present all three IEC nomenclature systems including their variants in full length. For further information please refer to the IEC Standards, listed in Section 8.4 ((Annex 1)). A short characterization of the different designation systems is given in Section 8.6 ((Annex 3)).

The problem of battery designation was already highlighted in 1990 by an article in a consumer journal entitled "Big Confusion in Battery Nomenclature" [234].

To the benefit of the consumers, the manufacturers, and the trade, it is hoped that future experts of the IEC will be able one day to take on the work again, i.e., to derive a unique and logical nomenclature system for all batteries, being in compliance with the IEC Directives, Part 2 and its principles and being suitable for data processing, as anyway required by today's information technology.

Furthermore it would be important especially for primary batteries to include into the nomenclature systems a well defined code, denoting the system's load capability. This matter is not only related to fit and function of the battery but also to safety. A relevant proposal being based on extensive experimental testing [235] was not supported. Presently the category of rate capability is not included in the designation, i.e., a difference of a factor 100 in load capability is not indicated on the primary battery. All that is indicated are system, voltage, and dimensional characteristics. This is in contrast to the IEC designation system for sealed nickel – cadmium batteries.

Table 22. Cylindrical batteries, popular size designations of ANSI and IEC

	Dimensions, mm		Size designations				
			Primary batteries			Secondary batteries	
No	1 Diameter	2 Heigth	3 Present ANSI	4 Former ANSI	5 IEC	6 IEC	7 IEC
1	10.5	44.5	24	AAA	R03	R03	R11/45
2	12	30.2	910	N	R1		R12/30
3	14.5	50.5	15	AA	R6	R6	R15/51
4	26.2	50	14	C	R14	R14	R26/50
5	34.2	61.5	13	D	R20	R20	R33/62

8.3.4. Closing Remark

Nevertheless, in spite of the deficiencies considerable progress has been made especially in areas as the standardization of new electrochemical systems and batteries and the issue of new IEC Standards on Battery Safety. Since IEC Standards are under constant review, it is hoped that existing discrepancies and nonconformities with the Directives, Part 2 will be eliminated in the foreseeable future.

8.4. Annex 1: IEC Standards on Batteries

Standards of TC21: Lead-Acid Batteries.

1) IEC 60095: Lead – Acid Starter Batteries
2) IEC 60254: Lead – Acid Traction Batteries
3) IEC 60896: Stationary Lead – Acid Batteries
4) IEC 61056: Portable Lead – Acid Cells and Batteries

Standards of SC21A: Secondary Cells and Batteries containing Alkaline or other Non-acid Electrolytes.

1) IEC 60285: Sealed Nickel – Cadmium Cylindrical Rechargeable Single Cells
2) IEC 60509: Sealed Nickel – Cadmium Button Rechargeable Single Cells
3) IEC 60622: Sealed Nickel – Cadmium Prismatic Rechargeable Single Cells
4) IEC 60623: Vented Nickel – Cadmium Prismatic Rechargeable Single Cells
5) IEC 60952: Aircraft Batteries
6) IEC 61150: Sealed Nickel – Cadmium Rechargeable Monobloc Batteries in Button Cell Design
7) IEC 61434: Secondary Cells and Batteries with Alkaline or other Non-acid Electrolyte: Rules for the Determination of the Current according to the Standards for Alkaline Secondary Cells and Batteries
8) IEC 61436: Secondary Cells and Batteries Containing Alkaline or other Non-acid Electrolytes: Sealed Rechargeable Nickel – Metal Hydride Single Cells
9) IEC 61440: Secondary Cells and Batteries Containing Alkaline or other Non-acid Electrolytes: Sealed Small Prismatic Rechargeable Nickel – Cadmium Single Cells
10) IEC 61808: Secondary Cells and Batteries Containing Alkaline or other Non-acid Electrolytes: Sealed Rechargeable Nickel – Metal Hydride Single Button Cells
11) IEC 61809: Secondary Cells and Batteries Containing Alkaline or other Non-acid Electrolytes: Safety Requirements for Portable Sealed Alkaline Secondary Cells and Batteries
12) IEC 61951: Secondary Cells and Batteries Containing Alkaline or other Non-acid Electrolytes: Portable Sealed Rechargeable Single Cells
13) IEC 61960: Secondary Lithium Cells and Batteries (This Product Standard includes also Safety Requirements).

Standards of TC35: Primary Batteries.

1) IEC 60086-1: Primary Batteries, General
2) IEC 60086-2: Primary Batteries, Physical and Electrical Specifications
3) IEC 60086-3: Watch Batteries
4) IEC 60086-4: Safety of Lithium Batteries
5) IEC 60086-5: Safety of Batteries with Aqueous Electrolyte

8.5. Annex 2: Designations by Manufacturers (Table 21)

Primary Batteries.

Rows 6 and 11. When looking at the designations given in rows 6 and 11 of columns 1 to 6, they all look different. None of them complies with the IEC designation. It is difficult even for the expert to recognize that all of them refer to the same type of carbon-zinc battery (row 6) and the same type of alkaline 9 V battery (row 11).

Row 3. Much easier is the case given in row 3. In most cases the designation CR2016 is used, which complies with the IEC designation for primary batteries, being standardized after October 1990. It actually was taken over from JIS just by agreement. For explanation: C means the electrochemical system (manganese dioxide – lithium), letter R is the shape letter (round), 20 means the diameter in millimeters and 16 denotes the height of the battery in tenth of millimeters. The designation CR2450 of the same series (however, not shown in Table 21) is interpretable on the same basis. In this case it must be known that 24 does not mean 24 mm but 24.5 mm.

Row 12 follows essentially also IEC recommendations, however, with exceptions. The correct designation following from the designation system, is given in row 12a. By way of exception the well-known designation 2CR5 was taken over.

Row 2 refers to an air – zinc button battery. This IEC designation is rarely reflected at all. The number 675 is used more frequently, which has to do with the tradition to designate a hearing aid button battery of this size (11.6 × 5.4 mm) with code no. 675 with preceding and/or succeeding letters, depending on manufacturer.

Row 8 is similar to row 2 in that the IEC designation for the high-rate cylindrical battery, i.e., CR17345 is rarely used. In some cases the first two letters CR are applied. As size code the code 123A is used, with preceding and/or succeeding letters, depending on manufacturer.

Row 7 refers to a cylindrical low-rate manganese dioxide – lithium battery, having a diameter of 14.5 mm and a height of 25 mm. The designation method is identical to the IEC method according to row 3. Some manufacturers, however, prefer a different size designation like, e.g., 1/2AA or 1/2 6L. The code AA is taken from the former ANSI standard (see Table 22) which refers to a battery size with 14.5 mm diameter and a height of 50.5 mm. The code 1/2AA refers to a height of 1/2 × 50.5 mm = 25 mm. The same is true for the size code 1/2 6, which refers to a R6 sized battery with letter L as suffix.

Secondary Batteries (Table 21). Like in the case of primary batteries, a logical background for the designations of secondary batteries can not be identified, apart from a few exceptions.

Rows 5 and 10. Row 5 refers to lithium-alloy button batteries. With the exception of the two-letter codes, their size code 2032 is identical to the IEC standard (see row 3 for explanation). Letter codes MT and VG may refer to different electrochemical systems.

Row 10 is an exception since the IEC size code 18650 is used by all manufacturers, however, not the IEC system and shape code ICR.

Row 9 is an example where none of the designations comply with the IEC designation. Some of the designations use size code AA (see row 7 for explanation).

Row 15 offers another case, where even the expert has difficulties to recognize that the manufacturers designation refer to the same type of lithium-ion battery.

8.6. Annex 3, Examples of IEC Nomenclature Systems for Batteries

IEC Nomenclature System 1. Example 1:The designation 6P40 (see IEC 1056-2, 1st ed. 1994) refers to a 6 V (6) prismatic lead acid battery (P), rated capacity $\underline{4}$ Ah ($\underline{40}$/10 Ah). A system letter is not used. Instead of battery dimensions or volume, the capacity is given.

Variant of IEC Nomenclature System 1. Example 2:The designation KCSH 15 (see IEC 60622, 2nd ed., 1988) refers to a sealed nickel – cadmium (K) prismatic single cell (C), employing sintered electrodes (S) for high rate (H) discharge, and a rated capacity of 15 Ah (15). The designation does not contain a shape letter. The rated capacity is given instead of battery dimensions or volume. The system letter K for nickel – cadmium stands for 1.2 V.

Attention is drawn to the deviations in structure and information, in comparison to example 1.

IEC Nomenclature System 2. Example 3:The designation KB116/055 (see IEC 509 2nd ed., 1988) refers to a nickel – cadmium (K) button (B) battery, having a diameter of 11.6 mm and a height of 5.5 mm. System letter K with no preceding figure means 1.2 V.

IEC Nomenclature System 3. Example 4:If the designation system according to IEC 6086-1, 1997 would be applied (nomenclature valid before October 1990) the designation of the nickel-cadmium battery in Example 3 would read KR44, letter K means nickel – cadmium, letter R means round and size code 44 denotes a battery having a diameter of 11.6 mm and a height of 5.4 mm.

Example 5:If the nomenclature system according to IEC 6086-1, 1997 (nomenclature valid after October 1990) would be applied, the designation for the same battery would change to KR1154. This size code is a variant of example 3: Figure 11 refers to the rounded down value of 11.6 mm and Figure 54 refers to the height of the battery in tenth of mm.

Example 6:The designation ICR18650 (see IEC 61960-1, 1st ed.) refers to a cylindrical (R), cobalt based (C), lithium-ion (I) secondary cell, having an approx. diameter of 18 mm and an approx. height of 65 mm. This example is a variant of example 5 in that two system letters (IC) are employed. The size code is derived on identical grounds.

Example 7:The designation ICR20/1050 (see IEC 61960-2) refers to a cylindrical (R), cobalt based (C), lithium-ion (I) secondary cell, having an approx. diameter of 20 mm and an approx. height of 105 mm. The slash (/) shall indicate, that the cell height is above 100 mm.

Example 8:The designation HF18/09/49 (IEC 61436, 1998) refers to a sealed nickel – metal hydride (H) prismatic single cell battery, designated as flat (F), having a width of 17.3 mm, a thickness of 8.3 mm and a height of 48.2 mm.

Example 9:When applying the dictum of IEC 61960-2, 1st ed., the designation of the battery in example 8 would read HP081748 (note: the size code of example 9 uses the sequence thickness, width, and height, whereas in example 8 the sequence width, thickness, height is used. Furthermore approximate dimensions are used in example 9 in contrast to example 8, which uses rounded up values with shape letter P instead of F.

Example 10:When applying the teaching of IEC 6086-1 (section A2) to the designation of example 9, it would read HP1948. The last two characters denote the height of 48.2 mm. The first two digits addresses the diagonal of the prismatic battery, as given by thickness and width and calculated via the Pythagorean theorem (integer value of 19.19 mm = 19 mm).

In conclusion: The different IEC nomenclature systems and their variants are actually not justified by technical reasons. They are non-uniform and can hardly be used for modern data processing. They are in general too long and therefore not consumer-friendly. Example: The designation LR61 of a small cylindrical alkaline battery has changed by now to LR8D425.

8.7. Annex 4, Denoting Electrochemical Systems

When addressing an electrochemical system according to the International Standards (see Section 8.4 ((Annex 1)), the positive electrode is addressed first, followed by the electrolyte and concluded with the negative electrode:

8.8. Example 1:

The manganese dioxide – ammonium chloride – zinc system

8.9. Example 2:

The nickel hydroxide–potassium hydroxide–metal hydride system

Since the correct designation is in general too long, popular abbreviations have come into use like the carbon – zinc system, the nickel – metal hydride system, the lead – acid or the lithium-ion system, etc.

A more correct abbreviation would be the designation by the system's formula:

	Designation by formula	Abbreviated formula
Example 1:	$MnO_2 - NH_4Cl - Zn$	$MnO_2 - Zn$
Example 2:	$NiOOH - KOH - MeH$	$Ni - MeH$

When naming only the positive and the negative electrode of the system, the positive should be named first and the negative second. For reasons of consistency this style was applied throughout this article.

In order to avoid ambiguities the type of electrolyte needs sometimes to be added like in the case of the $MnO_2 - Zn$ system, which also exists as alkaline version.

9. Battery Disposal, Environmental Protection

The growing attention that nowadays is paid to environmental protection also raises the question how to handle batteries after the end of their service life, since they often contain heavy metals and toxic substances. Run-down larger stationary and motive power batteries are usually replaced by a manufacturer and directed to a recycling plant to regain the valuable raw materials. This also applies to most automotive lead-acid batteries that were recycled to more than 96.5 % in the USA already in 1996 [236]. The situation, however, is different for the extremely fast growing market of small batteries which often are disposed of as municipal waste. Then their toxic constituents can be released into the environment from landfills or incinerators. This concerns more or less all battery systems.

A tremendous amount of primary batteries is used mainly in private homes, e.g., in flash lights, cameras, alarm clocks, and similar applications. This group includes button cells for primary use, e.g., in hearing aids, watches, and small calculators. Most of these batteries, however, do not contain heavy metals or other critical substances and therefore are not subject to official regulations in many countries.

Nickel – cadmium, Nickel – metal hydride, and lithium-ion batteries are increasingly connected to our daily life, for example in portable tools, such as drilling machines or electrical screw drivers, or other equipment, like mobile phones and notebooks. They exist as multicell "power packs", but also as single cells of cylindrical and prismatic shape or as button cells.

Small valve-regulated lead – acid batteries are used as standby batteries in household-fire alarm or similar security systems.

The problem with these small batteries is not the recycling itself, since suitable reprocessing methods and plants are available for most of them. The problem is the collection of these batteries, because they are indeterminably distributed in almost every home. Thus it would not have been sufficient to establish legislative regulations for recycling, but simultaneously effective collecting and sorting systems had to be installed to direct the various types of batteries to their corresponding recycling plant.

Parallel to these attempts, the industry made great efforts to reduce the toxic constituents in the batteries and to reduce the potential of environmental hazards. Thus today almost all primary batteries do no longer contain mercury, and an important incentive for the development of nickel-metal hydride batteries was the substitution of cadmium in the nickel-cadmium battery by a less toxic negative electrode.

9.1. Programs to Collect Disposed Batteries

The programs to handle disposed batteries are different in the various countries. The programs always include two aspects:

1) Legal regulations that concern the handling of hazardous waste
2) Programs to collect and sort the different batteries

Often the regulations have to be modified, when they do not allow the accumulation of hazardous waste, what necessarily is connected to the collection of batteries, containing substances that are defined as hazardous. In the USA, for example, this problem has been solved by the Resource Conservation and Recovery Act (RCRA) of 1976 (40 CFR) that regulates the handling of hazardous waste such as cadmium, but excludes residential waste. Thus batteries, discarded by households, are no longer subject to this regulation. This regulation was modified in 1995 (40 CFR, Part 273), and in 1996 President Clinton signed into law the so-called Battery Act

(*Mercury Containing and Rechargeable Battery Management Act*) that facilitated the collection of such batteries. The rechargeable types at that time were nickel – cadmium and valve-regulated lead – acid (VRLA) batteries. In these regulations, the latter are always designated as SSLA batteries (sealed small lead – acid batteries) [237]. Besides these general rules, details are handled different by the various states of the USA.

To solve the second problem, the collection of the batteries, in 1991 five major rechargeable battery manufacturers funded the Portable Rechargeable Battery Association (PRBA) to establish recycling programs and educational programs in the USA [238]. For the collection of the batteries the Rechargeable Battery Recycling Corporation (RBRC) was funded by the industry as an independent, nonprofit public service organization.

In Europe, the European Portable Battery Association (EPBA) established rules that act as a guide for all battery manufacturers in the EC member countries. In the meantime legislative regulations have been passed for the handling of disposed batteries everywhere, although these regulations vary in the different countries. As an official document, the EC directive 91/157 was adopted by the Environmental Counsel in 1991. It prescribed the collection of all batteries that contain lead, cadmium, or more than 0.025 % of mercury [239]. In Germany 1998 a more rigid decree came into force demanding that all spent batteries have to be collected, sorted, and recycled or disposed. In the same year a common collection system was established and the corresponding foundation (*Stiftung gemeinsames Rücknahmesystem, GRS*) founded in Hamburg as a nonprofit organization (details in [239]). Members are the main battery manufacturers and the Zentralverband der Elektrotechnik und Elektroindustrie e.V. (ZVEI) as the representative of the producers of battery-powered appliances. [A collecting system under the name ARGE – BAT (Arbeitsgemeinschaft Batterien) had been founded already in 1988, but failed since the importers refused to participate.]

All batteries are collected in special containers that are positioned in shops and public areas. The batteries are sorted and transported to recyclers or they are properly disposed. The total costs are estimated to 40 to 30 $\times$ 10^6 € per year which corresponds to about 0.026 € for a typical cell of the AA size [239].

Similar collecting systems have been established in a number of European countries and also in Japan.

9.1.1. The ISO Recycling Sign

To support the efforts to collect batteries, a special sign has been introduced worldwide, characterized by three chasing arrows, as shown in Figure 126. All lead – acid, nickel – cadmium, and nickel – metal hydride batteries are marked directly or indirectly (on the package) with this recycling sign. The sign means that the batteries can be reprocessed after the end of their service life. Batteries with this sign should never be disposed of with the normal household rubbish, but returned to the dealer or to special collecting points.

Figure 126. The ISO recycling sign (ISO Symbol 7000-1135) [240]

9.1.2. Sorting of the Collected Batteries

A general problem is caused by the fact that the collected small batteries form a mixture of all the systems and types that are on the market. Table 23 shows the sales of such batteries in the US between 1985 and 1992. A corresponding composition of the collected batteries has to be expected a few years later when these batteries are disposed.

A similar mixture of the collected batteries is to be expected today, however, the percentage of silver oxide and mercuric oxide batteries will be smaller, since those batteries were mainly used for special hearing aids and are now replaced by air – zinc batteries. On the other hand, nickel – metal hydride and lithium-ion batteries

Table 23. Percentage sales of domestic household batteries in the U.S, 1985 – 1992 [241]

Alkaline	Carbon – zinc	Nickel – cadmium	Air – zinc	Silver oxide	Mercuric oxide	Lithium
63.5 %	19.7 %	9.4 %	3.4 %	2.6 %	1.2 %	0.2 %

appeared on the market in the meantime and increasingly will contribute to the mix.

All these batteries must be sorted, since special recycling processes have to be used for the various battery systems. Separate collection would not make much sense, since the user often does not know which battery system he/she uses. Furthermore, it will happen rather often that batteries are thrown into the wrong bin.

The consequence is that sorting stations have to be installed to ensure effective separation of the various systems. Such stations are costly and always involve combinations of hand sorting and a number of automated steps [242]. In the latter, vibrating tables may separate different sizes of batteries. Magnetic separation and X-ray analysis can be used to discern the different battery systems. The battery can be transported from the conveyor belt into a collection device by mechanical forces or an air stream.

As an example, Table 24 shows results that were obtained in 1999 in Germany. The table lists the number of collected batteries compared to the delivery of new batteries in that year, both published by GRS [243], [244].

The figures of collected and delivered batteries in Table 24 cannot be compared directly, since most of the batteries collected in 1999 had been delivered in previous years. But the table shows that the ratio of the various systems within the collected mix reflects fairly well the delivered mix. This indicates that the collecting systems includes all battery systems, and that the market situation did not change too much during the previous years.

Manganese – zinc and carbon – zinc batteries constitute by far the largest number of collected batteries, according to their large share in the consumer market. The collected amounts of nickel – metal hydride and lithium-ion batteries were comparatively small in 1999, since both systems are rather young. The numbers of mercury oxide batteries, on the other hand, will diminish within the next years, since they are no longer manufactured in Europe.

Comparison of the total amount of collected batteries to that of delivered ones indicates that about 30 % of the delivered batteries were collected in 1999, although both figured cannot be compared, as already has been mentioned. According to [244] about 20 % of these batteries could be recycled while the residual 80 % had to be deposited, mainly on account of their mercury content (see Section 9.2).

9.2. Recycling of Batteries

The re-use of the raw materials must be the goal for the recycling processes to keep the expenses as low as possible. This means:

- The recycling process must result in materials that can compete with the primary materials or at least can be used instead of them. In lead – acid batteries, for example, primary lead is still preferred by many manufacturers as active material. Increasingly, however, recycled lead is refined so far that it can also be used for this purpose.
- The recycling method must be economical, i.e., the price of the secondary raw material must compete, at least approximately, with that of the primary raw material. This is mainly a question of the energy required, but labor cost may also be important, for example when the battery scrap has to be sorted laboriously.
- The method must be ecologically suitable, i.e., the recycling process itself must not cause environmental problems or generate residues that are difficult to dispose of.

The first item mainly concerns the purity of the recovered material. The purity achieved is a question of expenditure and thus is closely connected to the second item. But also the price of the primary metal is decisive and must be compared to that of the recycled material. It furthermore depends on the specification of the required material which kind of recycling process may be suitable and how far purification has to be carried.

Table 24. In Germany 1999 delivered and sorted batteries, data derived from [243], [244]

System	New batteries delivered in 1999		Disposed batteries collected in 1999	
	t	%	t	% of collection
Primary batteries				
Alkaline manganese + carbon – zinc	21 393	85.48	6012	79.56
Lithium	356	1.42	106	1.4
Air – zinc	75	0.30	75	1
Silver oxide + mercuric oxide	61	0.25	46	0.61
Secondary batteries				
Nickel – cadmium	1842	7.35	970	12.84
Nickel – metal hydride	676	2.70	7	0.09
Lithium-ion	324	1.29	47	0.2
Small lead – acid	290	1.16	232	3.08
Total	**25 017**	**100**	**7557**	**98.7**∗

∗1.3 % of the collected batteries could not be sorted.

Overall, the economic aspect of recycling is favored by the dramatic increase in dumping costs in most countries, and the dwindling possibilities of battery disposal in landfills greatly stimulate recycling efforts.

A fairly detailed review of the various recycling methods for batteries is given by a brochure edited 1991 by the Association of European Accumulator Manufacturers (EUROBAT) and the Association of European Dry Battery Manufacturers (EUROPILE) [245].

9.2.1. Recycling of Lead – Acid Batteries

Recycling of lead – acid batteries has been well established for decades, and most lead – acid batteries are actually recycled. Two main processes are used [246]:

1) The *blast-furnace* or *shaft-furnace process* which does not require previous separation of the battery components. The more or less smashed batteries, together with coke and smelting additives, are directly filled into the furnace. The organic components such as separators and containers are used as additional fuel, but they are lost. Lead sulfate and residual sulfuric acid are reduced and, together with added iron, form a slag of iron sulfide. Chlorine, which mainly originates from separators or spacers made of PVC, forms lead chloride, which is volatile at temperatures above 900 °C and escapes from the furnace together with the furnace gas. Lead chloride has to be collected by effective filter systems after cooling.
2) The *rotary furnace process* that requires preceding separation of the metallic parts of the battery from the other inorganic components. This means intensive pretreatment, including flotation processes to separate the different base materials according to their different specific weights. Sulfate, which forms a part of the active material as lead sulfate is removed with the aid of soda which converts the lead sulfate into lead carbonate which is further reduced to the metal. Only the metal-containing components are smelted in the rotary furnace.

In both cases, the crude lead obtained has to be refined by subsequent metallurgical processes.

The advantages and disadvantages of the processes are:

– The blast-furnace process requires practically no pretreatment and generates no wastewater that has to be neutralized and thoroughly decontaminated of residual lead. So it is economical. However, all the organic components of the battery are not recycled but lost (used as fuel).
– In the rotary-furnace process, all the organic components survive and may be recycled. The main problem is that a great variety of organic substances is used in batteries which can hardly be separated, and that these materials are contaminated with lead and other metals. But the increasing necessity for recycling everything may stimulate further development of this process.

The diluted acid is a special problem for economic reasons. It contains 10 to 20 wt % H_2SO_4; the rest of the sulfuric acid remains in the partly discharged plates of the scrapped batteries. But the diluted acid is contaminated, mainly with lead but also with other metals such as antimony, traces of copper, and occasionally nickel. So it cannot be reconcentrated, but has to be distilled to be reused as battery electrolyte. This distillation has to be carried out in a vacuum; otherwise sulfuric acid is decomposed before its boiling point of 338 °C is reached. Nowadays, this process is too expensive and the scrap acid is used for other chemical or metallurgical processes, like pickling, and is finally deposited as (heavy-metal-contaminated) gypsum ($CaSO_4$).

9.2.2. Recycling of Nickel – Cadmium Batteries

Recycling of larger nickel – cadmium batteries, used in stationary or traction applications, mainly concerns recovery of the valuable cadmium that forms about 15 % of the scrap weight. Cadmium can easily be regained by distillation. Recycling of small and especially sealed nickel – cadmium batteries on a larger scale was started at the end of the 1970s. Reasons for this rather late start were the above described problem of collecting these batteries and the more expensive treatment that is required. For this reason only about 15 % of the discarded nickel – cadmium batteries have been recycled in the U.S. in 1995 [241]. In Europe corresponding figures differ for the various countries between 5 and 50 % [247].

Problems connected with the recycling of nickel – cadmium batteries are:

- The collection of sealed nickel – cadmium batteries usually leads to a mixture with primary batteries. Therefore, sorting plants had to be established.
- The batteries first have to be dismantled before they can be treated.
- Iron and nickel, both of which are contained in these batteries, cannot be separated by the usual metallurgical processes. Both form an alloy that can only be used for production of stainless steel. The condition that the recycling process must result in materials that can be used again for battery production cannot be fulfilled for these components.

In the meantime the situation with small cells and batteries has changed, since collecting systems have been installed in many countries. Recycling capabilities are available as Table 25 shows.

According to the figures in Table 25, more than 30 000 t of nickel – cadmium batteries could be recycled. This figure is far above the amount of battery nowadays collected, and it surely could be increased. Thus, recycling itself is not the bottle-neck.

Predominantly pyrometallurgical processes are applied, especially in the plants that are dedicated NiCd recyclers (rows 4, 7, and 8 in Table 25).

In the NIFE process (row 7 in Table 25), larger cells are dismantled and positive and negative electrodes separated. The negative electrodes are rinsed to remove residual electrolyte and organic substances. Then the cadmium is distilled at 850 °C. The condensed metal is collected as a granulate that can directly be used as raw material in the production of new batteries. The positive plates are sold to steelworks where their content of nickel is used as an alloying additive. Plastic containers are cleaned and the material is granulated to be re-used. Small consumer batteries are shredded, than heated up to about 500 °C where the plastic components and the carbon are pyrolyzed. Then the rest is heated to 850 °C and the cadmium distilled as described above. The residuals that contain about 50 % of nickel are also sold the steelworks (more detailed description in [245]).

The SNAM/SAVAM process (row 8 in Table 25) is similar in principle. But here after dismantling the cells the material is pressed in cylindrical packages (900 mm diameter; 900 mm height) that are treated in electrical furnaces. Cadmium again is distilled at 900 °C (cf. also [245]).

INMETCO also applies a pyrometallurgical process that is similar to the above described ones. But this process forms only a small part of a much larger recycling operation to recover iron, chromium, and nickel for the stainless steel industry.

TNO/Esdex uses a hydrometallurgical process where cadmium is leached out of the

Table 25. Facilities that can recycle nickel – cadmium batteries and their capacity in t/a (1996)

∗ in 1996 planned figures (Table 8 in [247])

shredded batteries with the aid of hydrochloric acid. Cadmium is separated by solvent extraction (with tributylphosphate) and subsequently precipitated electrochemically as a rather pure metal. Nickel is recovered also by electrochemical deposition.

9.2.3. Recycling of Nickel – Metal Hydride Batteries

The recycling of nickel – metal hydride batteries is less attractive as a commercial process, since the raw materials of the negative electrode can hardly be regained and the hydrogen content of this alloys makes the handling of scrapped batteries more risky. But the fast increasing use of such batteries in many applications requires recycling capabilities.

In Germany NIREC developed a process (according to [242]) which is based on the recovery of the nickel content. In this process the batteries are shredded under vacuum, while the released hydrogen is continuously removed.

9.2.4. Recycling of Lithium-Ion Batteries

Nearly all lithium-ion batteries that are on the market contain cobalt in the form of cobalt oxide (CoO_2). Cobalt is a heavy metal and therefore should not be dumped in landfills. Furthermore, it is an expensive material that should be recovered. At the moment (2000), recycling processes are tested as pilot projects.

9.2.5. Recycling of Primary Batteries

In the recycling of primary batteries, a fundamental difference exists between batteries that contain mercury and others that are mercury-free. Formerly carbon – zinc (Leclanché) batteries and alkaline manganese dioxide batteries contained mercury on the order of 1 %, mainly employed to reduce self-discharge by hydrogen evolution at the zinc electrode. Today these batteries no longer contain any mercury, and only remainders of older or imported types may be found within the collected manifold. To allow an easy identification of the modern mercury-free batteries by the sorting machine, the European manufacturers cover them with a special varnish that can be detected by UV light.

9.2.5.1. Recycling of Mercury-Containing Batteries

Mercury gradually will diminish in waste batteries, because, as already mentioned, the addition of mercury has been abandoned in carbon – zinc and alkaline manganese batteries, which represent by far the largest share of primary batteries.

Batteries with mercury oxide as the active material of the positive electrode, which mainly had been used as button cells in hearing aids, will also disappear soon, because they are no longer produced.

Anyway it will take a number of years until mercury-containing batteries will have totally disappeared from in collected batteries. Until then they have to be sorted out and the mercury has to be recovered by vacuum distillation

(ALD Process). The removal of small mercury contents, however, is quite expensive.

9.2.5.2. Recycling of Mercury-Free Batteries

Primary lithium batteries contain organic electrolytes but no heavy metals. They do not contain substances that could be recovered and re-used as raw material for batteries.

1. Introduction

A bearing is a machine element that transmits loads or reaction forces to a shaft that rotates or oscillates relative to the bearing. *Radial* bearings are those where the forces act at right angles to the axis of rotation. *Thrust* bearings take up axial forces acting parallel to rotating shafts. Depending on how the load is carried and what kind of friction occurs, a distinction is made between *rolling-element bearings* and *sliding* or *plain bearings.*

The alloy designations and chemical compositions given in the tables are standardized by national and international organizations. Such organizations include the American Iron and Steel Institute (AISI, Washington, D.C., United States), American Society for Testing and Materials (ASTM, Philadelphia, Pa., United States), Society of Automotive Engineers (SAE, Warrendale, Pa., United States), British Standards Institution (BS, London, Great Britain), Deutsches Institut für Normung (DIN, Berlin, Federal Republic of Germany), and International Organization for Standardization (ISO, Genève, Switzerland, international).

2. Rolling-Element Bearings – Materials

In rolling-element bearings the load is carried by balls, needles, or rollers that are in intimate contact with the raceways. The starting friction of ball or roller bearings is only slightly higher than the operating friction, which itself is usually as low as that of hydrodynamic plain bearings. Rolling-element bearings are used for low to average speeds, the permissible speed decreasing as shaft diameter increases. The space occupied by a ball or roller bearing is relatively large. As a result of the comparatively long time before relubrication, maintenance expense is low. Bearings that support loads are subject to surface-pressure wear. Alternating tension and pressure stresses occur at the surface of the bearings. *Cracks* appear and propagate if the fatigue resistance of the bearing material is exceeded. In bearings subjected to high surface pressures, there may be Hertz-type stresses up to 3000 N/mm^2 [11]. Because of the great contact stresses between the rolling elements and the raceways, the bearing material must offer adequate strength at the operating temperature.

The most common material for ball and roller bearings is steel (→ Steel). Important examples are listed in Table 1. Usually throughhardening chromium steels having a carbon content of ≈ 1 % and a chromium content of 0.5 – 1.5 % are used up to 160 °C. The chromium content must be increased as the cross section of the rolling elements increases, the hardness ranging from 58 to 65 HRC (Rockwell hardness). Toughness and dimensional stability, which depend on the kind of thermal treatment and on the material selected, are important properties that must be taken into account.

Hardening is mainly the result of the transformation of austenite into metastable martensite, a transition that requires sufficiently rapid cooling rates. Tempering relieves stress and causes carbides to precipitate, especially from the martensite. The service life of bearing steel tends to increase with hardness, up to a maximum. Although great hardness does inhibit formation of cracks, once formed cracks propagate more rapidly because of the concentration of stress. The difference in hardness between the rolling element and the race also determines the life of a rolling-element bearing. For steel bearings, differences of 1 – 2 Rockwell (70 – 80 Vickers) give good results.

Generally, the service life of ball and roller bearings can be prolonged by reducing the content of nonmetallic oxide and sulfide impurities and by preventing the segregation of carbides. This all can be accomplished by remelting the bearing steel, e.g., by electro-slag remelting or vacuum remelting in an arc furnace or an electron-beam furnace.

Case-hardened steels, for example, SAE 4720, are used for bearing components of large dimensions, especially when conventional steels are difficult to harden through. Whereas in the case of normal hardening the steel must contain sufficient carbon from the very beginning to ensure that the desired hardness is reached, case-hardened steels have low carbon contents, for example, 0.2 %. The surface is carburized by annealing in carbonaceous media. Often the graded microstructure, with the hardness decreasing from the surface to the core, can be subjected to the same stresses as completely hardened structures. The higher the nickel content of the case-hardened steels the more uniform the hardness profile from surface to core, even in cases of mild oil tempering or martempering. The composition of hardened steels also determines the maximum operating temperature, as is shown in Table 1.

Steels with high chromium contents, such as X90CrMoV18, are resistant to corrosion and tempering up to ≈ 450 °C due to the fact that precipitation of carbon from martensite is prevented. These martensitic stainless steels can be used in rolling-element bearings operating up to 300 °C. For operating temperatures of 450 °C or even 540 °C, steels that retain their hardness are used: those containing molybdenum (4 or 8 %, respectively) along with chromium, vanadium, and tungsten. These elements are all carbide formers. Essentially, such steels are high-speed tool steels austenitized around 1100 °C. Tempering is carried out at ≈ 560 °C to precipitate finely dispersed carbides and ensure good creep resistance.

Figure 1. Schematic Stribeck curve and lubrication regions [7]
Region I. Hydrodynamic lubrication
Region II. Mixed lubrication
Region III. Boundary lubrication

For even higher operating temperatures, up to 800 °C, and oxidizing atmospheres, cobalt-base materials alloyed with chromium and tungsten, such as Stellite 3 or 100, are preferred. Basically they have an austenitic structure with a high carbide content. Even higher carbide contents are found in TiC cermet, where nickel acts as the metallic binder. Rolling-element bearings made of silicon nitride have been subjected to extraordinary high stress, e.g., in space flights. Plastic rolling bearings are used for lower specific loads at normal ambient temperatures, for example,

Table 1. Steels for rolling-element bearings [6]

Alloy designation	Specification standard*	Nominal composition, %		Maximum operating temperature, °C	Rockwell hardness, HRC	Characteristics; uses

* Standards: 1) DIN 17230 (FRG); 2) AISI-SAE Steel Classification (USA); 3) BS 970 (GB); 4) BS 4659.

in chemical plants. Conventional bearing cages made of plastic are becoming increasingly important.

3. Sliding Bearings

3.1. Tribology of Sliding Bearings

Since its definition in 1966, *tribology* has become widely recognized as a general concept embracing all aspects of the transmission and dissipation of energy and the dissipation of materials in mechanical equipment, including the topics friction, wear, and lubrication. The purpose of lubrication is to separate surfaces moving relative to one another with a film of material that can be sheared with low resistance without causing damage to the surfaces.

The mode of lubrication depends on the thickness of the lubricant. The *Stribeck curve* (Fig. 1) shows the general characteristic of lubricated moving surfaces and the relationship between friction coefficient f and a function of the lubricant viscosity η, the velocity v, and the normal load F_N (or pressure p), namely, $\eta\, v\, F_N^{-1}$. Surface roughness R, the operating conditions, and the separation of the surfaces h are also important factors. There are three main lubrication regions.

Fluid-film lubricated bearings are usually operated in region I, where the rigid surfaces are separated by a continuous lubricant film of thickness much larger than the combined surface roughness measure R. There is no direct physical contact between the surfaces, and wear processes cannot take place, except surface fatigue wear, cavitation wear, erosion, or corrosion. This is referred to as a *hydrodynamic lubrication.*

If at a constant load and lubricant viscosity the velocity is decreased, the lubricant film becomes thinner and the surfaces come closer together, producing the *mixed lubrication* associated with region II. The first asperity contacts occur: the load is carried partly by the fluid film and partly by the contacting asperities. In principle, all wear mechanisms, including abrasive wear, can take place. An even lower velocity ultimately results in considerably increased asperity interactions, the film thickness decreases down to a few molecules. In this region of *boundary lubrication,* the load is carried almost entirely by the deformation of the asperities, and the physical and chemical interactions at the solid – lubricant – solid interfaces determine the friction and wear. Although fluid-film lubricated bearings are designed to operate in region I, mixed and boundary lubrication do occur on starting and stopping machines. For some specific applications sliding bearings must be operated without lubricant – they must be run dry. The materials used have to be wearproof and scuffproof.

Sliding bearings do not operate reliably

1) if they run hot
2) if they show excessive wear

These two conditions are avoided by appropriate calculation, design, manufacture, and operation.

For hydrodynamically lubricated bearings, this involves:

1) selecting a lubricant of sufficiently high viscosity at operating temperature to reach fluid-film pressures sufficiently high to carry the load
2) avoiding excessive lubricant viscosity to reduce friction losses
3) assuring an adequate supply of lubricant and sufficient heat dissipation
4) designing and manufacturing bearings to produce a clearance between bearing and shaft appropriate for the formation of the required minimum fluid-film thickness.

Bearings operating in mixed and boundary lubrication regions are provided with reservoirs for the lubricant, e.g., impressed calottes or grooves in the sliding surface or pores of sintered material.

The demands on a sliding bearing are determined by the magnitude of forces to be transmitted and the space available for the bearing. The loads to be transmitted range from $\approx 10^2$ to 10^7 N for shaft diameters from 5 to 500 mm. The combination of load and available space for shaft and bearing produce specific loads that have to be taken up, statically and dynamically, by the bearing material as alternating and impact stresses. These stresses range over several orders of magnitude, reaching maximum values $> 100\,\mathrm{N/mm^2}$. Such stresses must always be considered in connection with the sliding velocities, which vary over a wide range [12]. The surrounding medium and the temperature must also be considered.

Even under usual, hydrodynamic conditions, the bearing materials are subjected to additional stresses as a result of cavitation, erosion, e.g., by dirt particles, and corrosion caused by additives or old lubricants.

Table 2. Definition of tribological terms (DIN 50282)

Term	Definition
Mechanical load limit	maximum possible load (force/projection area of bearing). If this limit is exceeded, the material will be subject to impermissible permanent deformation, forced rupture, or fatigue fracture
Load carrying capacity	load that a material can take with a specific kind of stress without exceeding the mechanical load limit and a defined amount of wear
Conformability	ability of a material to adapt to stresses by elastic or plastic deformations without permanently affecting the sliding behavior
Beddability	ability of a material to adapt to stresses by conformability and wear without permanently affecting the sliding behavior
Compatibility between bearing and shaft material	resistance to welding and scoring
Embeddability	ability of the bearing material to embed hard particles
Running-in characteristic	ability of a material to reduce the high initial friction and the high initial wear within a short time by adapting the sliding surfaces
Emergency-run characteristic	ability of a material to ensure sliding during a limited period of time if unforeseen unfavorable lubrication occurs

Deviations from normal operating conditions can result in solid contact between shaft and bearing in the mixed or boundary lubrication area, causing both elements to wear. Therefore, material properties and surface quality of shaft and bearing have to be selected with a view to the stress requirements. Specifications to aid in the

selection of compatible bearing and shaft materials are available [2]. The wide-ranging requirements for bearing materials have been defined for metallic antifriction materials in DIN 50282. The terms needed are defined in Table 2. The terms primarily describe properties that cannot be expressed numerically; the evaluations are qualitative – very good, good, etc.

3.2. Microstructure of Important Bearing Materials

Important properties of the base metals, including the modulus of elasticity, coefficient of thermal expansion, hardness, yield point, and fatigue resistance, both at room and elevated temperatures, correlate with the melting points of the metals. Therefore the melting point of the base bearing metal indicates application limits. Eespecially the mechanical properties depend also on the microstructure, which is affected by alloy constitution and production process.

The common metallic bearing materials have heterogeneous structures. Exceptions are the *copper – tin alloys* with less than 12 wt% tin, materials usually occurring as homogeneous supersaturated solid solutions (Fig. 2). The dissolved tin increases the load-carrying capacity because the solid solution is harder and more corrosion resistant to aged lubricants and additives. Grain-boundary hardening associated with the small grain size and work hardening increase the strength.

Figure 2. Microstructure of KS 934 (CuSn8P). The alloy is hardened by solid-solution hardening, grain-boundary hardening, and cold working, which is indicated by slip lines
100X

Heterogeneous bearing materials can be classified as follows:

1) materials where the microscopically distinguishable particles are softer than the matrix
2) materials where the particles are harder than the matrix
3) materials with both hard and soft particles in the matrix

Figure 3. Microstructure of KS 940 S (CuPb10Sn10) with steel backing. Soft particles of lead (dark) in the solid-solution hardened matrix (bright)
100X

Figure 4. Microstructure of KS 904.1 (white metal 10). Hard cuboids of SbSn in a soft eutectic matrix. The differing hardness of the two phases is shown by the micro-hardness impressions
100X

Case 1 includes the soft lead-containing tin bronzes, the tin- and zinc-containing multicomponent bronzes, and the tin-containing aluminum alloys. The lead that is insoluble in copper is distributed as soft particles in the lead-containing tin bronze matrix (Fig. 3). The dissolved tin increases the matrix hardness. While

the mechanical load-carrying capacity decreases as the content of soft particles increases, the sliding properties improve.

Figure 5. Microstructure of KS 960 (AlZn5SiCuPb) (Fig. 5 A). The distribution of Si (Fig. 5 B) and Pb (Fig. 5 C), revealed by microprobe analysis, indicate hard and soft phases
1500X

Case 2 includes the lead and tin alloys, the special brasses, and the aluminum alloy AlSi12CuMgNi. Figure 4 shows for the alloy PbSb15Sn10 the cubic particles of hard intermetallic SnSb in the soft eutectic matrix. Whereas hard iron – manganese silicides form in the special brass CuZn40Al2 during solidification, nearly all silicon in the high-silicon alloy AlSi12CuMgNi is distributed as hard particles. The matrix is precipitation-hardened by a fine distribution of magnesium- and silicon-containing particles that cannot be seen with an ordinary microscope.

Case 3 includes the aluminum alloy AlZn5SiCuPb. This alloy contains soft lead particles and hard silicon and aluminum silicide constituents, both in a matrix of medium hardness (Fig. 5). Also included in this group are the aluminum alloys AlSi4Cd and AlCd3CuNi, which are used in multilayer bearings.

The effects of the microstructure on some important properties are not yet understood quantitatively, especially because the structure may change considerably near the sliding surface during operation [13–15]. Qualitatively it is known that the usual hardening methods serve to improve the mechanical load carrying capacity, whereas the beddability essentially depends on the elastic and plastic properties of the base metal.

Figure 6. Microstructure of the multilayer bearing KS 941.1 S (CuPb22Sn) with overlay. The overlay of PbSn10Cu2 is deposited on steel-backed lead bronze
100X

Above all else the system properties are determined by the hard and soft phases. *Soft* components improve embeddability, the run-in characteristic, and the emergency-run characteristic. *Hard* phases increase wear resistance. The higher the content of hard-phase particles, the worse the embeddability and the emergency-run characteristic. Both hard and soft phases are able to limit scuffing. Under conditions of mixed and

boundary lubrication, these phases show little tendency to seize up [13].

Examples of the microstructure of *multilayer materials* are given in Figures 3 and 6. In both cases the steel supports the actual bearing material. For especially heavy loads, three-layer bearings are used: a layer, approximately 0.02 mm, of PbSn10Cu2 is electrodeposited onto a steel – lead bronze base (Fig. 6). This very soft, very thin overlay is then able to withstand the severe mechanical stresses. The overlay is beddable, embeddable, and serves as the sliding surface. The intermediate lead bronze ensures that the bearing remains operative even if the overlay is subjected to intensive wear.

Sintered metallic materials based on iron or copper contain a connected network of pores. The lubricant distributed in the pores serves as a reservoir for long service life, especially if the sliding velocities are low. These bearings are often referred to as maintenance-free bearings. Chemical compositions and microstructures that are not possible with melting techniques can be realized. An additional advantage is that solid lubrication can be employed.

The properties of *thermoplastics* can be determined by the selection of the monomers, the degree of cross-linkage, the degree of crystallization, and the polymerization process. The tribological behavior is determined by the micromolecular composition. The adhesion, which is undesirable for metallic materials, may be an advantage with polymers. For instance, PTFE firmly adheres to the steel shaft at low sliding velocities and high surface pressures, the individual lamellae or molecules of the PTFE sliding off each other, and the coefficient of friction is low [16], [17]. The principal disadvantages of polymers are their low thermal conductivity, their low wear resistance, and in many cases their high friction. Hard components (e.g., glass, metals, metal oxides) are used to increase the wear resistance; fillers (e.g., MoS_2, lead), to improve the sliding properties; and metallic particles (e.g., bronze), to increase the thermal conductivity. Since the load carrying capacity of thermoplastics is low, multilayer materials are often used. Figure 7 shows a plastic – metal multilayer bearing having a complex structure: A porous bronze structure (CuPb10Sn10) is sintered onto a steel strip. The pores of the bronze are filled with a PTFE – lead mixture by rolling.

Figure 7. Microstructure of the plastic – metal multilayer bearing Permaglide P 10. The porous CuPb10Sn10 sintered on a steel strip is filled with a PTFE – lead mixture by rolling 100X

Unlike thermoplastics, *thermosetting plastics* are tightly cross-linked by covalent or ionic bonds. Solid lubricants – graphite, MoS_2, PTFE – are used to improve sliding behavior.

The lubrication by *graphite* or *artificial carbon* running against steel shafts arises from their layer structure and the H_2O molecules present in the graphite lattice. These reduce the bonding forces between the lattice planes, and the planes easily slide against one another.

The strong covalent bond gives *ceramic* materials high compression strength, resistance to chemicals, and high melting temperatures. These properties make possible employing them as bearing materials, especially in aggressive media and at high temperatures.

3.3. Metallic Materials for Sliding Bearings

Three groups of metallic materials are used in bearings:

1) Metallic material for solid sliding bearings. These bearings consist of only one material. They are machined from castings or cold drawn tubes or roll-formed from strips. Copper, aluminum, tin, and lead alloys are used.
2) Multilayer metallic materials for thin-walled sliding bearings. These bearings are made from two or more layers of different composition. The preferred manufacturing processes include composite casting, composite sintering, cladding by rollbonding, and

galvanic deposition. Most common is steel-backed lead bronze. Also used is steel-backed aluminum alloy. Both are sometimes overlaid by lead – tin or lead – tin – copper alloys.

3) Sintered materials. Generally, sintered bearings consist of only one alloy, which is often based on iron or copper. They are manufactured by sintering of powdered metal to form shapes of defined porosity.

3.3.1. Metals for Solid Bearings

Lead and Tin Alloys. Combined with shafts usually made of unhardened steel, the lead and tin alloys offer good sliding properties. Because of their low strength, they require backings, mostly cast iron or steel, sometimes bronze, red brass, or brass. The composition and the most important properties of the lead and tin alloys known as *babbitt metals* are given in Table 3. Babbitt metals are used for bearings of big engines and heavy machinery. The specific load can be kept low by use of a large bearing, especially in the case of stationary machinery. For example, bearings for steam-turbine rotors carry specific loads of $\approx 1\ \mathrm{N/mm^2}$ at sliding velocities $\leqq 150$ m/s. The group of babbitt metals have the lowest melting point and the lowest hardness of the metallic bearing materials. The low hardness gives good embeddability for any dirt in the oil. The ductility allows good conformability to the shaft. The excellent sliding properties and emergency-run characteristic result from the microstructure. Babbitt metals offer good corrosion resistance to lube oils [18], [19].

The disadvantage of babbitt metals is that their mechanical load limit decreases sharply at higher temperatures, the maximum operating temperature being $\leqq 140\,^{\circ}\mathrm{C}$. Their low fatigue strength can be increased to some extent by design, manufacturing methods, and the use of modified alloys. Up to 0.15 % arsenic increases the strength of tin alloys. Arsenic concentrations up to and exceeding 1 % provide higher fatigue strength for lead alloys at elevated temperatures.

Reaction with the lube oil forms an oxide layer on lead alloys. This film gives lead alloys a higher resistance to scuffing at elevated temperatures than the tin alloys have. The stationary casting process or the more economic centrifugal casting process is used to manufacture bearing linings up to 6 mm thick from lead and tin alloys. Rapid dissipation of heat during solidification creates a fine-grained microstructure with good sliding properties and sufficient load carrying capacity.

Copper Alloys. The standard copper alloys for solid bearings are given for cast materials in Tables 4, 5, and 6 and for wrought materials in Table 7. The important cast materials are listed in order of increasing load carrying capacity, the result of increasing hardness, wear resistance, and fatigue strength.

Soft *lead – tin casting bronzes* (Table 4) have relatively low hardness but excellent emergency-run characteristic. In these respects they are similar to babbitt metals. They can withstand loads of $\approx 40\ \mathrm{N/mm^2}$ at average sliding velocities of ≈ 3 m/s. The shafts must be made from hardened steel. The manufacture of solid bearings from this and other copper alloys is usually by centrifugal or continuous casting. Lead contents > 20 % in alloys containing > 5 % tin are avoided because of the enlarge liquid miscibility gap. A fine dispersion of soft lead-rich eutectic particles is distributed throughout the cavities of the skeleton-type matrix. Too many such soft particles reduce the strength. Multilayer bearings are used when high mechanical load limits and good emergency-run characteristic are required.

Partial replacement of expensive tin by zinc combined with reduced lead content produces *copper – tin – zinc – lead casting alloys* (Table 5). The zinc improves the castability. These bronzes are usually produced for general mechanical engineering, where they are used for a variety of unproblematic uses involving small loads, low sliding velocities, and low operating temperatures. However, good lubrication is needed.

Tin bronzes, such as CuSn10P, or tin bronzes with low lead contents, such as CuSn12Pb2, are suitable for higher loads. Although their emergency-run characteristic is only average, these hard bearing materials have high load carrying capacity, offer good wear resistance and fatigue strength, and are insensitive to impact. Phosphorus prevents the oxidation of tin. Particles of the hard tin oxide distributed in the

bearing material may cause shaft scoring and increase the tendency to seize.

Special casting brasses and *multicomponent aluminum casting bronzes* (Table 6) belong to the group of high load carrying copper casting materials. The latter can carry even higher loads than the former. Because of their poor emergency-run characteristic, they can only be used if lubrication is good. The wear resistance of special brasses [20] is limited, and their fatigue strength diminishes when they are subjected to corrosion. For extremely high bearing loads at low sliding velocities, the wear- and corrosion-resisting aluminum multicomponent bronzes are effective even when there are impact and shock stresses. Their limited beddability and compatibility between bearing and shaft material require precision machining.

Copper wrought alloys are available as tubes or strips, and they are especially economical in the production of large quantities of solid bearings in the form of bushings or bushes and thrust washers. Tubes or strips for wrapped bushes are manufactured with as close a tolerance as possible from the materials listed in 7 by extruding and cold drawing or rolling of billets made by continuous or stationary casting. In this way machining times and material wastage in working the tin bronze CuSn8P and the special brass CuZn31Si1 are minimized. Slightly greater tolerances must be expected for materials such as CuZn40Al2 and most multicomponent aluminum bronzes. While casting materials cannot be work hardened, the mechanical properties of the copper wrought alloys can be improved by cold deformation.

The load carrying capacities of the various wrought and casting alloys are similar. Bearings made of tin bronzes such as CuSn8P, combined with hardened steel shafts, can be used to transmit high loads. Because of the hardness of this material, special attention should be paid to surface quality, the prevention of machining and alignment errors, and oil contamination. The load carrying capacity and the wear resistance of the special brass CuZn31Si1 are inferior to those of CuSn8P in spite of their similar mechanical properties. However, this low-priced special brass has proved its effectiveness for average loads and is widely used for wrapped bushes.

Aluminum Alloys. Solid bearings made from aluminum alloys are used to a limited extent only. Because the coefficient of thermal expansion of aluminum alloys is higher than that of the bearing housing material, e.g., cast iron and steel, problems develop at high temperatures regarding the press fit in the housing and the bearing clearance. However, the corrosion resistance of aluminum alloys is superior to that of copper materials, especially in sulfur-containing lube oils.

Aluminum alloys are listed in Table 8 in order of increasing load carrying capacity. The alloy AlSn6Cu, which contains soft tin particles, belongs to the bearing materials having good sliding properties. The harder alloy AlZn5SiCuPb can take slightly higher loads at average sliding velocities. Both materials are used for the main bearings of combustion engines with specific loads of $\approx 40\,\mathrm{N/mm^2}$ at sliding velocities of $\approx 15\,\mathrm{m/s}$, although such a high sliding velocity requires an additional overlay. The alloy AlSi12CuMgNi is a high wear-resisting material that permits high loads. However, the emergency-run characteristic is less good, and only low sliding velocities are permissible at high loads. This alloy is then preferred for high, even impact-type load conditions involving oscillating sliding motion, e.g., piston pin bushes with specific loads $\leqq 80\,\mathrm{N/mm^2}$ and a sliding velocity of $\approx 0.2\,\mathrm{m/s}$. This alloy is also used for floating bushes, e.g., in waste gas turbochargers. In this case the specific load of about $0.5\,\mathrm{N/mm^2}$

is so low that a maximum sliding velocity of 25 m/s can be permitted.

3.3.2. Materials for Metallic Multilayer Thin-Walled Bearings

The plain bearings in combustion engines have to fulfill demands that cannot be met by one material: high load carrying capacity and fatigue strength at temperatures up to ≈ 180 °C must be combined with high sliding velocities. The emergency-run characteristic must be adequate, and beddability and embeddability should be good. Despite small dimensions and wall thicknesses, the press fit in the housing bore must be tight even at high operating temperatures.

Such requirements are best met by multilayer materials. The steel backing ensures perfect press fit in the housing bore and gives the composite material the necessary fatigue strength by backing the bearing alloy, thus increasing its mechanical load limit. Then it is possible to use soft bearing alloys based on lead, tin, copper, and aluminum, all alloys characterized by good emergency-run characteristic but low fatigue strength, to produce high load carrying sliding bearings.

The steel backing usually consists of a low-carbon steel whose composition depends on the manufacturing process chosen for the production of the multilayer plain bearing. Since multilayer plain bearings, especially for small and medium-sized engines, are produced in large quantities, the production starts from steel strips coated with bearing alloy. The coating is carried out in a continuous process where the ac-

tual bearing material is cast on, sintered on, or rollbonded to the steel strip.

The thickness of the bearing alloy is usually 0.2 – 0.6 mm when the bearings are finished. Often an additional, ≈ 0.02-mm-thick electroplated overlay of tin-containing lead alloy is provided to further improve the sliding properties, thus making a three-layer metal bearing.

Steel-Backed Lead and Tin Alloys. Lead and tin alloys for thin-walled steel composite bearings, such as PbSb15SnAs and SnSb8Cu4 (Table 3), owe their use to their excellent emergency-run characteristic as well as their good compatibility and embeddability. Hardened steel shafts are not required. However, the use of these multilayer bearings is restricted because of their low fatigue strength and permissible temperature, these limits being slightly higher for lead alloys than for tin alloys. Bearing metal thicknesses of 0.1 – 0.5 mm can carry specific loads up to ≈ 18 N/mm². The lead or tin alloys for the manufacture of steel composite materials are cast onto a tinned steel strip to get good bonding. The rapid heat dissipation during manufacture produces a fine-grained microstructure with good sliding properties.

Steel-Backed Copper Alloys. Lead bronzes containing tin (Table 9) have proved especially successful as bearing materials when combined with steel backing. Materials containing a large proportion of the soft structure component, e.g., those with high lead contents, are characterized by good emergency-run characteristic and embeddability. This permits high sliding velocities. The higher the tin content the higher the hardness, the load carrying capacity, and the corrosion resistance.

There are two different processes for the industrial production of steel-backed composite materials: (1) the strip casting process, where the copper alloy is cast onto a steel strip, and (2) the sintering – rolling – sintering process, where

atomized powdered alloy is sintered on the steel strip in a three-step process. Specifically, the copper alloy particles are spread on the steel strip and sintered in an inert-gas atmosphere. The porous alloy layer is compacted by rolling and finally sintered again in an inert-gas atmosphere.

The alloy CuPb30 has an excellent emergency-run characteristic because of its high lead content; however, load carrying capacity and corrosion resistance are limited. This alloy is employed for wrapped bushes for hydraulic pumps and automatic gears. A lead bronze that finds widespread use in overlaid multilayer bearings is CuPb24Sn. It has good emergency-run characteristic and good fatigue strength owing to the steel backing. Main bearings and connecting rod bearings in combustion engines are its most important use. Specific loads $\leqq 70\,\mathrm{N/mm^2}$ and sliding velocities $\leqq 20\,\mathrm{m/s}$ are encountered.

** Standards: 1) ISO 4383 (international); 2) DIN/ISO 4383 (FRG); 3) SAE-J 459/J 460 (USA).

The alloy CuPb24Sn4 is slightly harder due to its greater tin content. It is suitable for average to high load carrying capacity combined with a good emergency-run characteristic. The corrosion resistance is good. This alloy is used in wrapped bushes and thrust washers under loads $\leqq 50\,N/mm^2$ and sliding velocities $\leqq 10\,m/s$, for example, in gears, piston compressors, and pumps. The alloy CuPb10Sn10 is characterized by a high mechanical load limit combined with a high wear resistance. The high tin content is the reason for the corrosion resistance to old

lube oils. The emergency-run characteristic is, however, low, so only low sliding velocities are permissible. Typical applications are piston pin bushes for combustion engines (specific loads of 140 N/mm^2 at a sliding velocity of 0.2 m/s) as well as wrapped bushes and thrust washers for gears.

Steel-Backed Aluminum Materials. The positive effects of a steel backing have permitted aluminum alloys, with their normally restricting properties at elevated temperatures, to gain in significance. The most important components are tin, copper, silicon, zinc, and cadmium. Generally corrosion resistance to sulfur-containing lube oils is good. Tin forms soft structure constituents and improves the emergency-run characteristic; silicon, like copper, increases the load carrying capacity. Industrial production of these multilayer composite materials involves cladding by roll-bonding. The aluminum alloy and steel are bonded at various temperatures in the roll gap while subject to great deformation. The aluminum alloys for multilayer materials are compiled in Table 10.

In the case of the alloy AlSn20Cu finely distributed tin particles are embedded in an aluminum – copper matrix. This high tin content ensures an excellent emergency-run characteristic even at high sliding velocities, but the fatigue life is limited, and therefore only average loads are possible. The most important uses are main bearings and thrust washers in combustion engines. For specific loads $\leqq 45$ N/mm^2 and sliding velocities $\leqq 20$ m/s, no additional overlay is necessary. Owing to the good emergencyrun characteristic as well as the excellent wear resistance, AlSn20Cu is also employed for all kinds of pumps for liquid. The material AlSn6Cu is suitable for high loads and has good emergency-run characteristic. It is used in main and connecting rod bearings of combustion engines. An additional overlay is necessary, and hardened steel shafts are recommendable. The load limit is ≈ 60 N/mm^2 for sliding velocities $\leqq 20$ m/s.

In respect to properties and applications the alloys AlSi4Cd and AlCd3CuNi are similar to AlSn6Cu. A material of high strength but limited emergency-run characteristic is the alloy AlSi11Cu, which is used in heavy load carrying connecting rod bearings in turbo-charged diesel engines. In this case, an additional overlay is necessary. Bearing loads $\leqq 70$ N/mm^2 and sliding velocities $\leqq 20$ m/s are permissible. The advantages of the alloy AlZn4,5SiCuPb are high load carrying capacity and good wear resistance. The emergency-run characteristic is adequate. It is also used for the heavy load carrying connecting rod bearings in turbo-charged diesel engines. This alloy requires an additional overlay as well as hardened steel shafts. The permissible bearing loads and sliding velocities are similar to those of the alloy AlSi11Cu.

Overlay Alloys. Steel-backed copper or aluminum alloys for main and connecting rod bearings in internal combustion engines almost always require additional electrodeposited sliding layers about 0.02 mm thick. Thicker layers are possible, though the fatigue life is shortened. Between the bearing alloys and the overlay there is a nickel barrier electrodeposited to a thickness of ≈ 0.002 mm. This layer (1) prevents diffusion of tin, which would lead to the formation of brittle phases in the copper alloy, or (2) ensures perfect adhesion to the aluminum alloy. The electroplated overlay alloys are compiled in Table 11. The alloy PbSn10Cu2 is probably the most widely used. Its tin content makes it corrosion resistant to old lube oils. The copper content increases the load carrying capacity. Greater copper contents, up to ≈ 6 %, have been used, and even higher contents, up to ≈ 15 %, are used in special cases. Such overlays give good operating results with heavy load carrying connecting rod bearings in turbo-charged diesel engines. The properties of PbSn10 are similar to those of PbSn10Cu2, but it has a slightly lower load carrying capacity. The PbIn7 overlay is comparable to PbSn10. The nickel barrier is not needed with PbIn7.

3.3.3. Sintered Materials

An important characteristic of sintered material is the pore volume, which ranges from ≈ 15 to ≈ 25 %. The materials listed in Table 12, which have a pore volume of ≈ 20 %, are the ones most widely used. The powder-metallurgy method of production results in a coherent pore network that has a high storage volume for lubricants owing to the capillary effect. The base metals for the sintered materials are powdered copper and

iron. The sintered bronze SINT B 50 has a composition comparable to that of conventional tin bronze and is characterized by a relatively good dynamic load carrying capacity of $\approx 5\,N/mm^2$ at 1 m/s. Graphite in the SINT B 51 material improves the low noise properties at the expense of the load carrying capacity. Compared with SINT B 50 sintered bronze, SINT B 00 sintered iron is characterized by a lower load carrying capacity, of $\approx 3\,N/mm^2$ at 1 m/s. Higher loads are permissible if copper, $\leqq 5$ %, is present. More copper changes the properties and makes them similar to those of sintered bronze. Depending on the lube oil, the maximum service life temperature of sintered bearing materials ranges between 90 and 180 °C [22]. Because of their low

noise level, sintered bearings are employed in almost all fields of technology, especially for fine mechanics and in automobiles. Solid lubricants other than graphite, e.g., sulfides, have been tried [23]. Bearings of sintered materials are produced by compacting mixtures of powdered metals in press molds and then sintering below the melting point of the main alloy components. Post-calibration ensures that bearings of high accuracy are obtained [24].

3.4. Plastics for Sliding Bearings

Plastics are used for plain bearings if their special properties, e.g., chemical resistance, insulating capacity, or attenuation capacity, are required. This occurs where plain bearings are operated with mixed or boundary lubrication or have to run dry, or where their use offers economic advantages. The main applications for dry bearings are the following:

1) vacuum operations or aggressive media, where there are no fluid lubricants
2) food industry, etc., where contamination by lubricants must be avoided
3) maintenance-free operations, where there is no checking or changing of lubricant

Plastics can be used for both solid and multilayer bearings.

3.4.1. Plastics for Solid Bearings

If compared with metals, *thermoplastics* (Table 13) are characterized by low density, low modulus of elasticity, good resistance to corrosion, high attenuation, and low lubricant requirements. Their disadvantages are low mechanical load capacity, inferior thermal conductivities, and high coefficients of thermal expansion. These three drawbacks and the considerable swelling in moist atmosphere have to be taken into account when designing the bearing clearance.

Fillers may be used to modify the properties of thermoplastics (Table 14). If the fillers are harder than the matrix, the mechanical properties are usually improved. For example, glass fibers improve the properties of polyamides. Softer fillers lower mechanical strength, for example, POM + PTFE. For dry bearings, fillers serve above all to increase wear resistance (graphite, glass, metal), to decrease the coefficient of friction (PTFE, lead, MoS_2), or to increase the thermal conductivity (bronze).

Unlike those of most metallic bearing materials, the mechanical properties of thermoplastics change considerably between $-40\,°C$ and $+100\,°C$. Since the macromolecular structure of the plastics can, moreover, be destroyed gradually as a result of extended exposure to elevated temperatures, the permanent service life temperature of the plastics with low melting temperatures (listed in Table 13) is $\approx 100\,°C$. PTFE and polyimide can be used up to about $260\,°C$.

Usually steel shafts are used in combination with plastic plain bearings. Independent of the type of plastic, the most favorable sliding conditions are reached if the Rockwell hardness of the steel surface is more than 50 HRC. A major factor affecting the sliding behavior is the roughness of the mating material. In general, the smoother the mating metal the lower the frictional wear of the plastic. In the case of sensitive plastics, e.g., PTFE and HDPE, wear can be minimized by using a metallic mating surface of slight roughness, which, however, may increase the coefficient of sliding friction.

The limits of load carrying capacity are determined by the resistance to compression and the temperature. With plain bearings of PA 6 having wall thicknesses 3 – 4 mm, average specific loads of $14\,N/mm^2$ are permissible for very low sliding velocities at $20\,°C$. Fiberglass-filled PA 6 can withstand average specific bearing loads of $24\,N/mm^2$. For higher sliding velocities, the $(p \times v)$ value is generally the load limit, however, only as a guide, since the limit is defined by the sliding surface temperature. For PA 6 bearings of 1 mm wall thickness, the $(p \times v)$ value for dry running operation is $0.07\,N/mm^2 \times m/s$ for $v = 0.1 - 1.5\,m/s$. For thick-walled bearings, 3 mm, however, the $(p \times v)$ value is only $0.04\,N/mm^2 \times m/s$. Since thermoplastics tend to become viscous at slightly elevated temperatures – a reversible process – accurate bearing shapes can often be manufactured by injection or compression molding. This is especially economical for long-run production.

Table 12. Sintered materials for bearings [21]

Standard grade	Material	Nominal composition, %	Open porosity, %	Density, g/cm³	Radial crushing strength, N/mm² min.	Elongation, % min.	Brinell hardness, HB min.	Characteristics [22]; uses
SINT-B-00 P 012*	iron	C 0.3 Cu 0–1 rest Fe	20 ± 2.5	6.0–6.4	80	3	30	standard material, average requirements for load and noise

SINT-C-51 P 4023			15 ± 2.5	7.0–7.5	124	2.5		

* All "P" designations are from ISO 5755 (1980).

Thermosetting plastics based on epoxy or phenolic resin with solid lubricants such as graphite, MoS_2, or PTFE are primarily used as dry bearing materials. Then such bearings can be subjected to loads $\leqq 1$ N/mm² at sliding velocities of 1 m/s. They are manufactured by molding of powdery granulates followed by a heat treatment to increase strength. This hardening involves cross-linking.

Greater surface pressures with very low sliding velocities can be taken by phenolic resins reinforced by asbestos or cotton yarns. Bushes and bearings are manufactured from tubes produced by a winding process. Such bearings are especially suited for water lubrication (water lubricated roll-neck bearings, marine stern tubes). Synthetic resin bearings based on phenol – formaldehyde containing chip- or striplike fillers of paper or textiles are often used where exposure to dust and dirt has to be expected, for example, in agricultural machinery, construction machinery, cement mills, and roll mills.

3.4.2. Materials for Plastic Multilayer Thin-Walled Bearings

The metal – plastic composite structure combines the good properties of plastics with the good properties of metals. Metal – plastic composites are able to take higher mechanical loads than plastic bearings. The greater thermal conductivity of the metal component allows higher (p × v) values. These two advantages are most important for dry running and boundary lubrication. Plastic multilayer bearings are used for hydrodynamic lubrication where occasional mixed-friction operation has to be expected. The usual lubricants are employed.

Maintenance-free plastic – metal multilayer bearings of the type shown in Figure 7 allow

[a] Properties of dry specimens. [b] DIN 53479. [c] DIN 53457, 4 point bend. [d] DIN 53455. [e] Transformation temperature.

(p×v) values of $1.8\,N/mm^2 \times m/s$ for continuous dry running. Experience shows that the sliding velocity should be kept $\leqq 2$ m/s for dry running and $\leqq 3$ m/s with lubrication. Table 15 lists metal – plastic composite materials.

Because of its chemical resistance and high service life temperature, PTFE is used most often. Plastics such as POM and PVDF are also used. Fillers may be incorporated.

To fabricate a composite material, for example, that illustrated in Figure 7, a 0.2 – 0.3 mm thick lead-bronze layer with a pore volume of ≈ 35 % is sintered onto a steel backing. The pores of this bronze are filled with a pasty blend of PTFE and lead in a rolling process that also applies a layer 0.01 – 0.03 mm thick. The impregnated strip is hardened at ≈ 320 °C.

3.5. Artificial Carbon and Graphite for Solid Sliding Bearings

Graphite has good sliding properties and is used as a solid lubricant in sintered materials (see Table 12) and thermoplastics (Table 14). In addition, artificial carbon and graphite are used for solid plain bearings, which are characterized by good dry-running behavior at temperatures up to 350 or 500 °C in oxidizing atmospheres. Both are resistant to chemicals in wet operations.

Artificial carbon bearings are used in drying units and kilns and in operations involving aggressive liquids or media that may affect the operational reliability of the bearing. Other important properties of these materials are a low coefficient of thermal expansion, ranging between 2.5×10^{-6} and $4.0 \times 10^{-6}\,K^{-1}$, and a thermal conductivity that can be compared to that of metals. In dry operation, the friction coeffi-

* Transformation temperature.

cient of graphite is 0.1 – 0.2 if the air is humid or other vapors surround the bearing (see Section 3.2). In a high vacuum, the coefficients of friction increase by a factor of 10. In normal dry operation, a dynamic load of 0.2 N/mm² can be permitted for bearings made from heat-hardened carbon at sliding velocities of 0.5 m/s, whereas 0.8 N/mm² must not be exceeded for bearings made from electrographite at the same velocity. In wet operation, higher sliding velocities are permissible, e.g., up to 4 m/s for a specific load of about 5 N/mm², this in the case of geared pumps.

Sliding bearings of artificial carbon require shafts having a high surface quality. A shaft roughness of $R_z = 0.5 - 1.0\,\mu m$ is desirable. Hardened shafts, for example, hardened chromium steels, are advantageous. A porosity of artificial carbon between 10 and 15 % enables additional impregnation, both with metal and synthetic resins. Impregnation increases the load carrying capacity for a dry bearing up to ≈ 3.7 N/mm² if the electrographite is impregnated with a special salt. However, the temperature limit is lower. For example, artificial carbon impregnated with lead or synthetic resin can only be employed ≦ 180 °C.

Graphite and artificial carbon are brittle. For high-temperature use, artificial carbon bearings shrunk onto a steel ring give the best press fit in the housing bore. Presently there is no standard available for materials, and therefore manufacturers' information has to be used. Design features are standardized in DIN 1850.

Artificial carbon bearings are fabricated from compacted blanks and annealed. Heat-hardened carbon is obtained at 1200 – 1300 °C. Firing temperatures of 2800 – 3000 °C produce electrographite quality especially suitable for plain bearings. The burnt blanks are finished by cutting.

3.6. Ceramic Materials for Solid Sliding Bearings

Of the ceramic materials, only *alumina* is widely used for speciality solid plain bearings. Like graphite and artificial carbon, alumina is resistant to aggressive media and high temperatures.

Table 15. Thermoplastic composite bearing materials [27]

Material	Additions	Operating temperature, °C	Thermal conductivity, $W m^{-1} K^{-1}$	Characteristics
Steel backing with porous sintered tin or lead–tin bronze layer, filling and finish of polytetrafluoroethylene and additives	Pb, MoS_2, graphite, in special cases no additives	− 200 to + 280, continuous operation ≤ 260	40	dry running, boundary lubrication, hydrodynamic lubrication
Bronze backing with porous sintered tin or lead–tin bronze layer, filling and finish of polytetrafluoroethylene and additives	Pb, MoS_2, graphite, in special cases no additives		50	
Steel backing with porous sintered tin or lead–tin bronze, coated with thermosetting plastics, e.g., POM, PVDF	PTFE, Pb	− 40 to + 130, continuous operation ≤ 100	2–10	initial lubrication, boundary lubrication, hydrodynamic lubrication
Easily shapable re-sintered tin bronze fabric, embedded in polytetrafluoroethylene sheet with additives	graphite, glass fiber powdered tin bronze, MoS_2, in special cases no additives	− 200 to + 260, higher for short intervals	0.8	dry running, initial lubrication, hydrodynamic lubrication
Easily shapable fabric of stainless steel, embedded in polytetrafluoroethylene sheet with additives			0.8	
Steel backing with glued on polytetrafluoroethylene mixed fabric, filling of phenolic resin	polyester fabric	− 200 to + 180, higher for short intervals	0.8 without backing	dry running, initial lubrication, hydrodynamic lubrication
Backing of steel, stainless steel, or nonferrous metals with glued-on polytetrafluoroethylene mixed fabric, filling of phenolic resin	fabric of glass fiber, bronze, cotton	− 200 to + 180, higher for short intervals	0.8 without backing	dry running, initial lubrication, hydrodynamic lubrication

It is very hard and is resistant to abrasive wear. However, it is brittle and has a tendency to break. Its very high wear resistance is useful for circulation pumps for hot-water heating systems. Solid particles carried in the water circuit are not embedded in the bearing, but crushed between the aluminum oxide bearing and shaft.

Wear resistance and insensitivity make this material useful in supply pumps for polluted or aggressive liquids. Alumina is useful for valves.

Aluminum oxide plain bearings are fabricated from molded parts and sintered. The blanks are cut with diamond tools.

3.7. Soft Rubber for Sliding Bearings

Important criteria for the use of soft rubber as a bearing material are its low coefficient of friction and its high elastic deformability, shock absorption capacity, and wear resistance. Soft rubber, having a Shore Hardness A between 33 and 81, is used in water-lubricated plain bearings, especially for water pumps, since this material is completely resistant to water, even seawater, and has a high wear resistance. In addition, soft rubber is resistant to almost all nonoxidizing acids and alkaline solutions below 65 °C. On the other hand, it is very sensitive to oil and petroleum products, which cause the rubber to swell and lose its elasticity and strength. However, some special grades, such as butyl rubber, are resistant.

Unlike other plain bearings water-lubricated soft-rubber radial plain bearings have an elastic gap size as a consequence of the great deformability of rubber. The elastic deformability partially compensates for the low viscosity of the lubricant water [28]. As a result less precision is required to fabricate rubber bearings than for other water-lubricated bearings, such as bronze or artificial carbon.

Generally soft rubber plain bearings with backings are usually made from metals, e.g., CuSn5Zn5Pb5, but can be made from thermosetting plastics where the rubber layer is vulcanized into the backing.

Soft rubber is very sensitive to temperature fluctuations because of its low thermal conductivity, and the highest operating temperature ranges from 70 to 100 °C depending on the type of rubber. Lubrication and cooling has to be sufficient. The rubber sliding layer often forms a polygon with longitudinal grooves. In the case of larger bearings, especially with marine shaft bearings, individual rubber-lined metal rods with interspaces are mounted around the periphery of the backing brass. The hard particles in the water are temporarily embedded in the elastic rubber before they pass into the next groove and are flushed away. However, the grooves increase the coefficient of friction and lead to mixed lubrication operation. Despite their excellent sliding properties, smooth circular cylindrical rubber bearings without grooves are not used. If the bearing runs dry, the rubber is soon destroyed as a result of the quickly rising temperature [29].

Soft rubber can be used with water lubrication at $v = 2$ m/s and $p = 1$ N/mm^2. Rubber containing ≈ 50 % graphite had an increased limit load [30].

3.8. Practical Selection of Materials

In addition to knowing the tribological fundamentals, the following factors are important in selecting the bearing material best suited for a specific application:

1) load, specified by kind, intensity, and direction
2) sliding speed, specified by range and kind – either oscillating, rotating, or linear
3) space available for installation and bearing dimensions
4) temperature
5) environmental conditions, such as wetness, humidity, corrosive media, dirt, dust, and external vibration
6) lubrication (or dry), specified by type, rate, and supply

Other aspects are reliability in operation, exchangeability in case of damage, and the availability of specific bearing materials and designs. Last, but not least, is the cost, not only production costs but also downtime costs if the bearing has to be replaced.

The wide variety of proven bearing materials on the market is the result of the variety of situations in which plain bearings serve. The practical know-how of the bearing manufacturers can be useful in selecting a specific material.

1. Introduction

Beer is described as a beverage containing alcohol, extract, and carbon dioxide. Beer is prepared from barley malt, raw hops or other hop products, brewing water, and top- or bottom-fermenting yeast. The alcohol must be produced exclusively from these ingredients, which are converted to fermentable products during the brewing process. Barley malt may be combined with wheat malt, unmalted cereal adjuncts (raw grain), and other extract-containing materials. Legal regulations concerning raw materials and additives as well as rules for listing these vary from one country to another.

To obtain barley malt, the grain is germinated under controlled conditions; the controls comprise moisture content, germination temperature, the ratio of oxygen to carbon dioxide in the germinating grain, and germinating time. *Green malt* is formed once a certain increase in enzyme activity and a partial degradation of the starchy endosperm have taken place; this latter process is called by the brewer *modification*. Green malt is then processed into *kiln* or *brew-*

ing malt by drying. This malt is subsequently milled (ground) and mixed with brewing water. During the subsequent procedure, called *mashing*, high molecular mass components of malt are degraded by enzymes at specific well-defined temperatures (*rest periods*). The suspension is filtered to separate the liquid, called *wort*, from the spent grains. This process is called *lautering*. The wort is subsequently boiled with the addition of hops; this causes a coagulation of constituents, which are then called *hot trub* or *break*. They are separated together with the solids from the hops (*hot trub removal*). The clarified wort is subsequently cooled to the *pitching temperature* required by the fermentation method and the yeast strain used. The fermentation process is initiated by *pitching*: this consists of saturating the cold wort with air and adding cultured yeast. The fermentable low molecular mass components of the wort are converted to ethanol and numerous aroma compounds (fermentation byproducts) according to the metabolism of the yeast strain. After maturing to taste and enriching with carbon dioxide produced by fermentation, the beer is filtered to clearness and bottled.

The *extract of original wort* (original extract; original gravity) is defined as the mass fraction of nonvolatile, dissolved extract substances in the unfermented, cold pitching wort. During fermentation most of these substances are metabolized by the yeast, and the content of extract continually decreases. The extract of original wort can, however, be determined in samples taken during fermentation and in the finished beer, provided that the alcohol concentration and the real extract (extract contained in the dealcoholized beer) are both known.

The *degree of attenuation* is defined as the ratio of fermented extract to original extract, expressed as a percentage. The *attenuation limit* indicates the maximum amount of extract that the yeast will ferment.

Furthermore a distinction has to be made between top- and bottom-fermenting types of beer. The *top-fermenting yeast* rises to the surface at the end of the main fermentation process, whereas the *bottom-fermenting yeast* settles at the bottom. Both yeast types differ morphologically, in their enzyme composition, and in their physiological behavior.

The nomenclature of beer types is determined by their general production method (see Chap. 3). Typical beer designations have developed from the natural chemical composition of the water in various regions, e.g., Pilsener, Munich, Dortmunder.

In the Federal Republic of Germany, teaching and research in the area of brewing is concentrated at the technical universities of Berlin and of Munich-Weihenstephan. The universities of other European countries and of Japan also have formidable research capacities. Furthermore, in numerous countries there are research facilities operated jointly with the brewing industry. In addition, there are the laboratories of the large brewing companies, which have contributed greatly to the level of knowledge currently available. Results of research are discussed at scientific meetings in Europe (European Brewery Convention, EBC) and at international meetings in the United States, South America, Australia, and Japan.

History. The word beer comes from the Latin word "bibere" (to drink), which is the origin of the Old English word "bēor" (the brewed), akin to the Old High German word "bior", from which also the French word "bière", the Italian "birra", the East European "pivo", and the Spanish "cerveza" developed.

The roots of beer production, however, go back much farther to the first agrarian societies, the Sumerers. They used a variety of grain called emmer (*Triticum dicoccum*) which was dehusked and baked to give flat bread. The flat breads were soaked in water and then allowed to ferment spontaneously through the action of wild yeasts. The Babylonians developed the art of brewing further and distinguished between twenty different types of beer, in which the emmer and barley content as well as the strength of the beer were closely regulated. The "Codex Hammurabi" contained regulations regarding the quality of beer and described strict punishment for beer adulterators.

The Egyptians refined further the art of beer brewing and the legal requirements. They made the grain germinate and eliminated the soaked pieces of bread by sieving.

The Jews, Greeks, Romans, and Germanic peoples all knew beer, but partly preferred wine as a drink. From the seventh century, malting and brewing processes were researched with great experimental zeal, mainly in German monas-

teries. In the following centuries, brewing and dipensing rights were loaned out to several monasteries. It was also the monks who first used hops as a flavoring agent. From the fourteenth century, hops were generally accepted as an additive; earlier, tree bark, bitter herbs, and berries were added to the brew.

Until the sixteenth century, only the spontaneous top fermentation, which occurs at higher temperature, was known; later, bottom fermentation also was discovered.

War changed drinking habits because of the destruction of cultural values. Bavaria, for instance, became a beer country only after the Thirty Years' War, when its vineyards were destroyed.

Beer as it is known today was only made possible through numerous inventions in technology. Hot air kilns, steam engines, refrigerating machines, and filtration equipment enabled brewers to work throughout the year. Increasingly, more precise control of the brewing process also became available. The most significant improvement in quality was finally accomplished after the invention of the microscope: yeasts were found to cause the alcoholic fermentation. At the end of the nineteenth century, yeasts were cultivated and introduced into the brewery as pure strains.

Purity Law. Laws that regulate the production of beer have always been regarded as consumer protecting regulations. One of these statutory regulations was laid down by the Bavarian dukes Wilhelm IV and Ludwig X at the State Parliament at Ingolstadt on April 23, 1516; the law was accepted and is known today as the *Purity Law* (Reinheitsgebot). It requires that only barley (barley malt), hops, and water are to be used for the production of beer; yeast, as the fourth raw material, was only mentioned for the first time in 1551. Germany, Greece, and Switzerland brew according to this very strict law, the oldest in the world that pertains to food processing.

Other sources of extract and numerous additives and brewing aids are permitted in countries elsewhere. Because brewing technology does not require additives and chemicals for the production of beer of a consistently high quality, the Purity Law brewers insist on the maintenance of the Purity Law.

2. Raw Materials

2.1. Starch-Containing Raw Materials

For further information, see also the articles on → Cereals and Cereals Products, and on → Starch.

2.1.1. Malting Barley

Barley belongs to the family of grasses (*Gramineae*) and is found in various forms. First, a distinction is made between summer barley (spring sowing) and winter barley (late fall sowing), and second, between two-row and multiple-row barleys, according to the number of blossoms on the stalk. Multiple-row barleys produce malts richer in husks, protein, and enzymes, which may prove advantageous when using unmalted grain adjuncts. Two-row barley is divided into two main groups: the straight barley, and the "nodding" barley, whose ear hangs down during maturation. Two-row spring barley (*Hordeum distichum nutans*) has the best malting and brewing properties; the most important varieties of spring barley in Europe are Barke (Germany, Denmark), Chariot (UK), Optic (France, Denmark, UK), Pasadena (Germany, Denmark), Reggae (Netherlands), and Scarlett (France, Germany, Denmark, Netherlands). Two-row winter barley varieties are Plaisant (France), Pipkin (UK), Tiffany (Germany), and Vanessa (Germany). The advantages of barley over other grains that could be used for malting are the easier regulation and control of the germination process, the superior taste of beer made with barley, and the brewing technology available. Barley grows best in a humid climate and on soils with moderate contents of nutritients. The husks produce a filter bed for lautering, and the enzyme complement is advantageous for bringing about the desired modification. A similar uniform development of kernels as in the two-row spring barley can only be achieved in the newly-bred two-row winter barley varieties. Mixtures of spring and winter barleys cause technological difficulties in the malting process. Because the developmental rhythms of the two types of barley are different, the germination process occurs unevenly when processing mixed charges. These problems may be

overcome by using separate malting processes, but processing difficulties can be expected in the brewery in connection with lautering, fermentation, and the filterability of the beer; an impaired beer stability can also be expected.

Quality Requirements. Minimum specifications are laid down in the EC quality standard. Moreover, the maltster puts further requirements on his raw material:

Germinative ability > 98 %
Screening: > 90 % > 2.5 mm (Vollgerste)
Raw protein content < 11.5 %
Extract > 80 %
Attenuation limit > 80 %

Smell, color, gloss, and husk fineness are checked by manual appraisement. Further mechanical, chemical, and physiological inspection methods are listed in [29], [30].

The most important malting attribute of barley lies in its *germinative vitality*, which is defined as the percentage of kernels that initiate germination in the very beginning of the malting process. Freshly harvested barley must pass through a post-maturation period. This dormancy may be shortened by physical or chemical methods.

The germinative energy is a measure of germination maturity: it indicates how many grains have actually germinated after three days under conditions that are similar to those used in practice. A further indicator of maltability is the sensitivity of the barley to an overexposure to water during steeping (water sensitivity); the importance of this criterion has declined following the application of extended air rest periods during steeping.

The standardization of pilot-scale malting methods has become an indispensable aid for the assessment of barley and optimization of malting technology parameters; furthermore these methods provide reliable criteria in the selection of newly-bred barley varieties for planting.

Directions for the cultivation, storage, and physiological preservation of brewing barley, as well as detailed descriptions of its morphology and breeding, may be found in the literature [8], [10], [12], [13].

Chemical Composition. The chemical composition of brewing barley versus a pale malt is shown in Table 1. The moisture content, which is especially relevant to the storage quality of freshly harvested barley, may range from 12 to 20 %; 10 to 12 % are optimal for storage. As shown in Table 2, the moisture content is the limiting factor for storage. The α-glucans (amylose and amylopectin of the starch) are the most important carbohydrates in barley. Other carbohydrate components include β-glucans (cellulose, hemicellulose, gums), pentosans, as well as minute portions of low molecular mass sugars. Proteins are especially important for maltability, yeast nutrition, foam, taste, and the stability of the beer. Lipids are only partially used up during malting, the remainder staying mainly in the spent grains. Other important components are phosphates (about 0.3 %), minerals (2.5 – 3.5 %), vitamins (about 0.5×10^{-3}%), and phenolic substances (about 0.2 %). The enzymes of barley and of malt, as well as their effects during mashing, are shown in Table 4.

2.1.2. Malting Wheat

For some top-fermenting beers (see Section 3.4) wheat malt is added in order to achieve a special flavor quality. Brewing wheat should contain 11.5 – 12.5 % protein. Its extract yield is in the range of 83 to 87 %.

2.1.3. Unmalted Grains

Economic reasons or insufficient supplies of brewing barley or brewing malt have resulted in obtaining part of the starch by the addition of other, unmalted grain types. These *adjuncts* may account for up to 30 % of the grist in Europe, and up to 50 % in the United States. However, the success of this practice requires the use of very high enzyme-containing and protein-rich barley malts. In many countries these adjuncts are defined as replacement material for brewing malt, which add mostly carbohydrates to the wort; their use must be legally permitted.

Unmalted barley does not present any economic advantage over barley malt. Lower yields are achieved and frequently insufficient conversion in the brewhouse has to be corrected by adding enzymes produced microbially. Beers produced in this manner contain less nitrogen,

Table 1. The chemical composition of brewing barley and malt (mass fractions in %)

	Malting barley		Malt	
	As is	Dry matter	As is	Dry matter
Moisture	12 – 14		4 – 5	
Starch	55 – 57	64 – 66	56 – 58	58 – 60
Other non-nitrogen extract compounds	12 – 14	14 – 16	16 – 18	17 – 19
Protein	9 – 10.5	10 – 12	8.5 – 10	9 – 11
Fiber	4	4.5	5	5.2
Minerals	2.5	2.8	2.4	2.5
Fat	2	2.3	2	2.1

Table 2. Maximum storage time for maintaining malting barley quality under different storage conditions

Storage temperature	Seed moisture content			
	10 %	12 %	14 %	16 %
8 °C	7.5 years	2.5 years	1 year	170 days
10 °C	6 years	2 years	300 days	140 days
12 °C	5 years	1.6 years	240 days	110 days
14 °C	3.8 years	1.3 years	190 days	85 days
16 °C	3 years	1 year	150 days	65 days

have a lower attenuation limit, and display better head retention, but filtration is more difficult.

Unmalted wheat. Partially unmalted wheat is sometimes added to the mash. Its composition is similar to that of barley. With a moisture content of 15 %, wheat contains 65 % starch and other carbohydrates, 12 – 14 % protein, and 1.7 % fat.

Rice is processed as broken rice. This by-product of table rice production must be pure white. The moisture content is 12 – 13 %; other concentrations (expressed on a dry basis) are: extract 93 – 95 %, fat 0.5 – 0.7 %, protein 8 – 9 %. Rice starch gelatinizes at 65 – 70 °C, sometimes only at about 80 °C. The co-processing of rice generally results in very light and dry beers.

Corn (maize) is processed as corn starch, flakes, or larger corn grits, and is popular because extract yields range from 87 to 91 % after the removal of the oil-rich embryo. Moisture content should not exceed 12 – 13 %; protein content (dry basis) is in the range of 8.5 – 9 %; a residual fat content of less than 1 % in the grits is not harmful to head retention. Addition of corn results in sweetish, full-bodied beers. Commercial corn starch is practically free from protein and fat. The final yield is about 103 %, because of the addition of water during enzymatic hydrolysis

Sorghum, as a malt additive, has only regional importance in Africa.

2.1.4. Other Sources of Extract

Other sources of extract are processed *starch preparations* and *carbohydrates* in fermentable low molecular mass form. Besides starch flour itself, syrups frequently are used, which are manufactured from grain or starch flour by enzymatic or acidic hydrolysis. All syrups have an extract content of about 80 %, while their fermentability is in the range of 40 – 78 %. They are added to the wort kettle. The concentration of the wort may be increased in this manner to 15 – 18 % without affecting the further process development adversely (see Section 3.5.4).

Sugar is added to the wort kettle shortly before the end of boiling in order to raise the proportion of fermentable extract. Amounts up to 15 % yield very soft beers with a wine-like flavor. For malt beers and nutrient beers, sugar is added to the filtered beer in order to achieve the desired character and extract of original wort. Sugar is added as sucrose, as invert sugar, or as glucose. For nutrient beers caramelized brewing sugar may be added. The extract content of the sugar solution is between 65 and 85 %, depending on consistency and quality.

2.2. Hops and Hop Products

Hops added to the wort are an indispensable ingredient for many reasons [7], [9]. They impart a bitter taste to the beer, a specific aroma, and promote clarification. Furthermore, they are considered to have foam-improving qualities. Hops also are believed to act as an antiseptic in beer. The hop plant, *Humulus lupulus*, is a hardy, dioecious, climbing plant, and belongs to the hemp family. Only female vines are planted in hop farms; propagation is carried out by perpetuating vegetative clones. Hop cultivation requires special climatic conditions and a soil varying in texture from sandy to muddy. The hop cones are of primary interest to the brewer. They represent clusters of blossoms on the female plant and grow despite an absence of pollination. Hops are picked in August or September. Yellowish-green, sticky, cup-like glands (lupulin glands) are located on the inner sides of the inner and outer bracteoles; they contain the aromatic and bitter substances.

Hops are classified according to their origin and type; for similar varieties, the influence of origin dominates. The cultivated types have been obtained by separation according to shape. Classification by type in the EC is made on the basis of the content of compounds responsible for the bitter taste and flavor:

1) *EC List A aroma hops*: Hallertauer, Hersbrucker, Perle, Saazer, Spalter, Tettnanger
2) *EC List B bitter hops*: Brewers Gold, Magnum, Northern Brewer, Nugget, Target, Taurus

According to the certification policy within the EC hop market law, since 1978 producers of hops are required to designate varieties and to indicate origin. The most important hop-producing countries, together with their quantities harvested, are listed in Chapter 6. Hops can be judged on the basis of manual classification (appearance, color, pest infestation), whereas brewing values can only be determined by chemical analysis. Table 3 lists the most important components found in hops. The bitter acids (α- and β-acids) and the aroma substances (hopoils) are of great importance both from the viewpoint of brewing technology and for the taste of the beer.

Table 3. The chemical composition of hops (mass fraction in %)

	As is	Dry matter
Water	9 – 12	
α-Acids	2 – 17	2.2 – 13.5
β-Acids	2 – 10	2.2 – 11.2
Hop oils	0.5 – 2.5	0.6 – 2.8
Non-nitrogen extract compounds	4 – 9	4.5 – 10
Protein	15 – 21	13 – 22
Fiber	10 – 17	11 – 19
Polyphenols	3 – 8	4.5 – 16
Minerals	7 – 11	8 – 12
Lipids and waxes	up to 3	up to 3.4
Fatty acids	0.05 – 0.2	0.06 – 0.22

2.2.1. Resins

The bitter constituents of hops consist of α-acids (humulones), β-acids (lupulones), soft resins, and the oxidation products of bitter acids, called hard resins. The brewing value of the individual fractions varies and depends on their solubility in beer and wort and on their bitterness potential.

The α-acids are the most important of these bitter components because of their high bitterness potential.

R = $CH_2CH(CH_3)_2$: Humulone [*23510-81-8*]

R = $CH(CH_3)_2$: Cohumulone [*511-25-1*]

R = $CH(CH_3)CH_2CH_3$: Adhumulone [*475-36-5*]

R = $CH_2CH_2CH(CH_3)_2$: Prehumulone [*59122-94-0*]

R = CH_2CH_3: Post humulone

The soft resins produce a lower bitterness level, about 10 – 33 % of the intensity produced by humulones. Hard resins are even less bitter. The β-acids are not bitter at all. The solubility of the α-acids is very dependent on the pH value. At the pH of the wort, these substances will dissolve to only a limited degree. In beer itself, α-acids are found only in very limited quantities, because they are isomerized during the boiling process whereas the remaining acids are removed during fermentation as part of the foam cover. The α-acids isomerize to iso-α-acids, e.g., *cis*- and *trans*-isohumulone. All α-acids and their isomerization products have approximately the same bitterness.

cis-Isohumulone

[1534-03-8]

trans-Isohumulone

[467-72-1]

The isomerization products are significantly more soluble than the original α-acids, and are stable at the pH value of beer. During the isomerization process the following α-acid derivatives also are formed: *cis*- and *trans*-alloisohumulones, abeoisohumulones (oxidized isohumulones), antiisohumulones, spiroisohumulones, humulinic acids, and their various homologues; for details, see [2].

The lupulones (β-acids) are insoluble at the normal pH value of the wort. They do not isomerize during boiling, and are largely removed with the spent hops and the trub without being utilized. Lupulone differs from humulone by a side chain on the C_3 of the six-membered ring, and gives rise to the same homologues as humulone. During storage, lupulones oxidize to β-soft resins, which are soluble in the wort and in beer and also impart bitterness to the latter.

2.2.2. Hop Oil

The volatile and nonvolatile aromatic components of hops also determine hop quality. The aromatic content of hops is influenced not only by the variety but also very much by the drying and storing conditions and by processing.

The relative amounts of the almost insoluble sesquiterpenes, such as humulenes, farnesenes, and β-caryophyllenes, can be used to distinguish between the different varieties.

The mono- and sesquiterpenes become more soluble by oxidation, i.e., they are converted to epoxides; during fermentation they are partly transformed by the yeast to the corresponding sesquiterpene alcohols and can therefore contribute to the aroma of the beer.

Some volatile compounds (aldehydes, ketones, alcohols, and esters) are also produced during aging of the hops by side-chain breakdown of the bitter acids. Most of these, however, evaporate during wort boiling.

2.2.3. Polyphenols

Hops contain a number of phenolic components and derivatives of low molecular mass, such as phenolic acids (e.g., *p*-hydroxycoumaric, gallic, ferulic, protocatechinic, and caffeic acid), coloring components (catechins, flavones, and anthocyanidines), and polycondensated substances with strong tanning properties, which can originate from procyanidines. Hop polyphenols play a role in the establishment of the intrinsic colloidal stability of beer [21], [22]. The net result of boiling is a dramatic change in the already complex polyphenol composition of wort. Part of the complexity can undoubtedly be ascribed to the ready oxidation and the ease of polymerization of many polyphenols. Most of the hop polyphenols are removed during wort boiling by precipitation with proteins. The addition of hop polyphenols does not alter the foam consistency and color of beer, but very high dosages of hop polyphenols and long boiling times may adversely affect the colloidal stability. Low molecular mass polyphenols act as antioxidants and hence have a beneficial effect on beer flavor stability. The positive effects of low molecular mass polyphenols on human health are reported in Chapter 7.

2.2.4. Processing of Hops and Hop Products

After harvesting, the hop cones must be dried from a moisture content of 75 – 80 % to a level of 10 – 12 % using low temperature and strong air circulation. The hops are sulfurized before being packed into bales or compressed into ballots. Hops should be stored in cool, dry, dark areas at about 0 °C to preserve their quality. Vacuum packing followed by impregnation with an inert gas is necessary if prolonged storage of the hop product is anticipated. High temperature, oxygen, moisture, and light will cause changes in the oil fraction of hops; bitter acids become resins and lose part of their bitterness potential, whereas the polyphenols transform into higher condensed products [32–34].

Various hop products find acceptance nowadays in the brewing industry because of their improved storage capacity, longer preservation

of quality, and simpler handling in the brewery. Regulations control the use of these products in various countries. Hops products can be classified into four general types:

Non-Isomerized Hop Products. In this type of product the α-acids remain unchanged during hop processing. To achieve sufficient isomerization during wort production they must be added to the kettle at the start of or during wort boiling. Products included in this category are:

Double compressed whole hops

Hop pellets type 90. By drying hops down to a moisture content of 6 – 9 % and grinding, a powder is obtained. The powder is usually pelletized and packed under inert conditions. Because these pellets possess a larger surface area, their components are more readily soluble than those from raw hops. Therefore, the use of hop pellets type 90 offers savings of 10 – 15 % in terms of α-acids. Pellets also occupy a considerable smaller volume than raw hops.

Hop pellets type 45. After drying, hops are deep-frozen to about – 30 °C and ground. Lupulin is separated from the cones and from other nonessential parts of the leaves by sieving at the same low temperature. This treatment also reduces the polyphenol concentration in the resulting hops, depending on the extent of removal of nonessential components. Furthermore, the content of undesired components such as nitrate or pesticides is reduced. The powder, which usually is pelleted, offers savings in terms of α-acids of about 15 % when compared with natural hops.

Stabilized hop pellets are produced by blending magnesium oxide or calcium oxide with the hop powder prior to pelletization. During the formation of the pellet, the α-acids react with magnesium ions to form salts, which isomerize to *iso*-α-acids during storage.

Hop Extracts. Solvents used for the extraction of hops include ethanol and carbon dioxide (supercritical or liquid). For the production of the extract the hops are ground, the valuable components are dissolved, and the solution is separated from the solid substances. In all production methods, the solvent is finally evaporated at 40 – 60 °C and reclaimed. The extracts are packed in cans.

Carbon dioxide and ethanol dissolve the α-acids quantitatively. During extraction with 90 % ethanol, isomerization of 10 % of the α-acids takes place. Carbon dioxide dissolves only traces of the hard resins under the prevailing extraction conditions for the removal of bitter substances.

The aroma-contributing components are quantitatively dissolved; losses caused by the evaporation of the solvent are minimal in the case of carbon dioxide and substantial with ethanol. In the process employing supercritical carbon dioxide, the extraction conditions are controlled by pressure and temperature. The composition of the resulting extract of aroma-contributing substances and resins can be controlled by fractionation.

Carbon dioxide does not dissolve tannins and hop proteins. These may be obtained during a secondary extraction step by the use of hot water. During one-step procedures using ethanol as solvent, a certtain proportion of tannins also is extracted, which can easily be removed by centrifugation.

All extract can be standardized to a defined α-acid content with hot water extracts of hops or glucose syrup. The savings in bitter substances when using extracts are aprroximately 10 % in terms of the amount of the α-acid.

Isomerized Hop Extracts. In these products, α-acids have been isomerized to iso-α-acids during processing. Unlike α-acid based products, iso-α-acid products can be added either during wort boiling or after fermentation, depending on the composition of the product. Isomerized hop products include:

Isomerized Hop Pellets. The α-acids of stabilized hop pellets are converted easily and quantitatively into the corresponding iso-α-acids by heat treatment at temperatures below 60 °C.

Isomerized Kettle Extracts. There are two basic methods for the production of isomerized kettle extracts. In the first method pure resin extract is heated in contact with aqueous potassium carbonate-hydroxide solution. This gives an isomerized kettle extract in which the iso-α-acids are present as

potassium salts. In the second method the pure resin extract is mixed and heated with magnesium oxide. No water is added during the isomerization process. In the magnesium salt form the extract is very viscous and not easy to handle. By treatment with a strong acid, the magnesium iso-α-acid salts are converted to the free acids. This extract can be handled similarly to a conventional pure resin extract.

Isomerized hop extract is used for dosing into cold, fermented beer and must therefore be of high purity and essentially free of insoluble hop resins.

Reduced isomerized hop extracts comprise three different reduced forms of iso-α-acids: extracts containing rho-iso-α-acids (dihydroiso-α-acids), those containing tetrahydroiso-α-acids and those containing hexahydroiso-α-acids.

Hop oil products are specifically used to impart aroma to beer. They include the following preparations:

Hop pellets type 100 are produced by simple compression of whole hops. Waste materials are removed, but the hops are not dried or milled prior to compression. The pellets are vacuum packed in order to preserve the quality of the oil during storage. Whole hop pellets are generally added to cask conditioned ales in order to impart the beer 'dry hop' aroma.

Oil-Rich Hop Extract. An extract, that has a higher than normal oil content, can be obtained by partial extraction with carbon dioxide or fractionation during production of pure resin extract with supercritical carbon dioxide or by addition of pure hop oil to pure resin extract.

Pure Hop Oil. A common method for isolating pure hop oil is a steam distillation of an extract under vacuum or atmospheric pressure.

Hop oil emulsions

Fractionated hop oils

Miscellaneous Hop Products. Specialty hop products are available, which do not contribute significantly to beer bitterness, but are used instead to prevent overfoaming in the kettle and ensure normal fermentation characteristics. These products include:

Base hop extracts

Purified β-acid fractions

2.3. Brewing Water

Natural water always comes as a highly diluted mineral salt solution; its chemical composition and the concentrations of various constituents usually are determined by the geology of the specific region of origin. In addition, impurities, organic substances, and organisms may subsequently enter the water. Because of their low concentration, the salts are almost completely dissociated into ions, which indirectly influence the quality of the beer.

Today almost any water can be made suitable for brewing but at a corresponding cost. Expensive water treatment is unavoidable if certain ions are present in such high concentrations as to be detrimental to the beer, e.g., an excessive amount of sodium chloride or more than 30 mg/L of nitrate ions. Nitrate is reduced during fermentation to nitrite, which is toxic to yeasts.

2.3.1. Salts

The total solids content of natural water usually is 50 – 2000 mg/L, with an average of ca. 500 mg/L. The following ions are predominantly found in the water:

Cations: H^+, Na^+, K^+, NH_4^+, Ca^{2+}, Mg^{2+}, Mn^{2+}, Fe^{3+}, Al^{3+}

Anions: OH^-, Cl^-, HCO_3^-, NO_3^-, NO_2^-, CO_3^{2-}, SO_4^{2-}, SiO_3^{2-}, PO_4^{3-}

Calcium and magnesium salts are most commonly found in natural waters. The sum of these two cations determines the total hardness of the water, which is expressed in milliequivalents per liter (mval/L). Carbonate, hydrogencarbonate (HCO_3^-), and free carbon dioxide have to be controlled carefully because of the corrosive nature of free carbon dioxide. The non-carbonate hardness is accounted for by salts of acids other than carbonic, e.g., sulfates. These salts remain dissolved during boiling [35].

Effects During Mashing. At the concentrations of mineral salts normally found in water, interactions with soluble components of the malt as well as various effects on the enzymes of the malt and on the ingredients derived from the hops are of practical importance, especially with regard to the net effect on the solubility of the α-acids. It is essential to observe how different ions present in the water, together with the malt ingredients, influence the pH values of the mash, the wort, and the beer. The phosphates of sodium, calcium, and magnesium are most effective in this regard. Further reactants include the potassium and calcium salts of such organic acids as lactic, malic, and succinic. The various hydrogencarbonates influence the acidity to varying extents, because the solubilities of the corresponding secondary or tertiary phosphates are different. Accordingly, the effect of magnesium hydrogencarbonate is greater than that of calcium hydrogencarbonate, because the secondary magnesium phosphate will remain in solution. The effect of sodium hydrogencarbonate is even more marked, because strongly alkaline tertiary sodium phosphate is formed, which remains in solution together with the secondary sodium phosphate. In addition, the precipitation of phosphates by calcium and magnesium ions results in a decreased buffering capacity of the mash, so that the pH may drop too rapidly during fermentation.

The alkalinity of the wort caused by hydrogen carbonates also affects the solubility behavior of the bitter substances present in hops. On the one hand, when the pH is increased, the solubility is increased, but an unpleasant, harsh bitterness is created in the beer. On the other hand, the ions of the alkaline-earth metals are able to compensate for the increase in pH caused by hydrogencarbonate. The following equation demonstrates this effect:

$$3\,Ca^{2+} + 4\,HPO_4^{2-} \rightarrow Ca_3(PO_4)_2 + 2\,H_2PO_4^-$$

Calcium ions convert the secondary phosphate to the acidic primary phosphate. Magnesium ions are only half as effective by comparison with calcium ions.

Alkalinity. The term alkalinity is used to designate the concentration of the hydrogencarbonate ions in water (→ Water, Chap. 6.1.). The "residual alkalinity" is calculated by subtracting the effect of the acidity-improving alkaline-earth ions from the effect of the acidity-destroying hydrogencarbonate ions:

$$\text{residual alkalinity} = \text{total alkalinity} - \left(\frac{\text{Ca hardness}}{3.5} + \frac{\text{Mg hardness}}{7}\right)$$

Hardness is given in degrees German hardness (dH). The total alkalinity is equal to the hardness linked to the presence of hydrogencarbonate ions.

The residual alkalinity indicates the suitability of the brewing water for the various varieties of beer. The residual alkalinity for pilsener should be below 35 ppm $CaCO_3$, and 90 – 110 ppm $CaCO_3$ for pale beer. Decreasing the residual alkalinity by 90 ppm $CaCO_3$ will lower the mash pH by 0.15 units. Should the residual alkalinity increase substantially, considerable disadvantages can be expected. The brewhouse yield is reduced by 2 % when the residual alkalinity is in the range of 180 – 210 ppm $CaCO_3$. Similarly, high values for residual alkalinity resulting in a mash pH of over 5.8 will reduce the effectiveness of most of the hydrolytic enzymes. As already mentioned, a high pH value causes a molecular solution of the α-acids, which will impair the bitter flavor of the beer. The release of polyphenols from the husks of barley malt will occur with greater ease in this pH range, and is acceptable only in the case of dark beer.

2.3.2. Brewing Water Treatment

Water used for brewing should correspond in quality to drinking water; it should be clear, colorless, and neutral in taste and smell. It should not contain heavy metals, especially iron and manganese, and should not be corrosive. Natural waters originate from many different geological formations and therefore very rarely conform to the quality required for brewing water. For this reason treatment is required before water from such sources can be used for brewing. The actual extent of water conditioning is governed by the concentrations of anions, the dissolved organic substances, and the presence of aggressive gases in the untreated water. Processing of brewing water also depends on the specific needs of

the brewer and on the particular beer required. The selection of a treatment method also is influenced by the prevailing laws.

Attention is directed to both the carbonate hardness and to the ratio of carbonate to non-carbonate hardness, which should be around 1 to 2 – 2.5. Bearing profitability in mind, the treatment methods mentioned in the following can be applied:

Heat Precipitation. Carbonates can be precipitated by boiling. However, this method is not economical.

Decarbonation. The simplest procedure for the precipitation of carbonates is to add milk of lime. The following components can be removed by $Ca(OH)_2$: free CO_2, $Ca(HCO_3)_2$, $Mg(HCO_3)_2$, and $MgCO_3$. For the latter, however, a pH of 10.5 – 11 is required. If the non-carbonate hardness in the raw water is higher than the magnesium hardness, quick or pressure decarbonation may be used. In this case, water and milk of lime are intensively mixed in a reaction vessel, where calcium carbonate precipitates as a coarse product that sediments well.

Variations in magnesium hardness are more problematic. If the magnesium hardness exceeds the non-carbonate hardness, slimy magnesium hydroxide will partly precipitate and clog the gravel filter bed; it can also contaminate the brewing water. To overcome this problem, a two-step *precipitation – decarbonation process* is used. In the first step, the calculated amount of milk of lime that is needed for the decarbonation and for the removal of magnesium is added to a partial stream of the raw water (two thirds). This is done in a superliming reactor, where both calcium carbonate and magnesium hydroxide are precipitated. This alkaline water subsequently reacts with the remaining one third of the raw water stream in a refining reactor. In this reactor, the excess lime is used to precipitate calcium carbonate whereas the magnesium carbonate of this 30 – 40 % stream remains in solution. The total water is finally collected in a storage tank after filtration through a gravel bed.

In order to control variability in the composition of raw water hydrogen ion exchange facilities can be installed at the end. This equipment will automatically be activated whenever the pH rises above a predetermined value. The procedure ensures extensive removal of the magnesium hardness. The brewing water thus obtained is very poor in carbonates, and does not contain an excess of free carbon dioxide after irrigation.

Ion Exchange (→ Ion Exchange). Brewing water can be readily deionized by using ion exchange resins, which require little space and facilitate a quicker throughput. The availability of food-grade ion exchange resins enables raw water to be processed to give water of any desired composition.

Cation exchangers can be either weakly or strongly acidic, depending on the anticipated load. Weakly acidic exchangers remove only the hydrogencarbonates (of Ca^{2+} and Mg^{2+}) from the raw water. During this process a large amount of free, corrosive CO_2 is liberated; this needs to be removed by blowing a countercurrent of air through the water. The remaining CO_2 reacts with milk of lime or marble to form $Ca(HCO_3)_2$; in this way slight hardening is achieved. Alternatively, the deionized water can be blended with raw water.

Strongly acidic ion exchangers operate in a similar manner. All cations are removed from the raw water, even those of the strong acids, and are replaced by hydrogen ions. These exchangers are especially effective with hardness caused by magnesium. The free mineral acids that are thus formed are neutralized with saturated milk of lime.

Anion exchange: SO_4^{2-}, Cl^-, and NO_3^- ions may be removed with anion exchangers; this will decrease non-carbonate hardness. Even though total deionization is not desirable in the production of brewing water, complete ion exchange enables the brewer to prepare brewing water from sources with widely differing compositions.

Electroosmosis. For total deionization by electroosmosis, investment and operating costs are much higher than in the treatment procedures described above. In addition, this procedure may be applied only if combined with other deionization methods. In a continuous-current field the salts in the water migrate towards the electrodes, which are separated by membranes. The water trapped between the membranes is appreciably lower in its salt content and can be run off.

Reverse Osmosis. Ions, molecules, and other small particles can also be removed from water by reverse osmosis. Additionally, table waters may be obtained from the resulting concentrate by proper sterilizing and carbonating procedures, provided that the ionic composition is appropriate.

Acid Addition. The addition of mineral acids, such as hydrochloric, sulfuric, or phosphoric acid, changes the carbonate hardness into non-carbonate hardness, but the total hardness remains unaltered.

Other Processes. Another important treatment may become necessary if bad-smelling or bad-tasting substances have to be removed. This can be achieved by installing an activated carbon filter upstream of the deionization equipment. Suspended matter is removed with flocculants and gravel bed filters, so as to avoid clogging of the downstream equipment.

Furthermore, such mineral salts as are found in natural water may be added to brewing water. Acceptable food-grade salts are: $CaCO_3$, $MgCO_3$, $CaCl_2$, $CaSO_4$, and NaCl.

2.4. Beer Yeasts

Brewery yeasts belong to the family of Saccharomycetaceae and the genus *Saccharomyces*. They have the main advantage that their cells propagate by budding. For the production of bottom-fermenting beers, *Saccharomyces carlsbergensis* are used, and for top-fermenting beers, *Saccharomyces cerevisiae* [36].

After the malt enzymes have been destroyed during wort boiling, the yeast provides the original wort with its enzyme system. Wort is not an ideal nutrient medium for yeast. In order to metabolize actively, the yeast must synthesize those substances it needs according to the wort composition. Depending on the syntheses required, the amounts of the metabolic products that are found in the fermenting substrate will differ. References to taxonomic and technological structure, morphological characteristics, chemical composition, propagation, metabolism, and yeast enzymes can be found under the appropriate keywords: → Ethanol, Chap. 5.1.; → Yeasts.

The pitching yeast should be selected as carefully as the other raw materials. Furthermore, its introduction into production, its crop after fermentation, and its further handling should be managed with great care. Short-term storage of yeast and aeration before pitching retains fermenting power and keeps the yeast in good physiological condition. If an infection with organisms detrimental to beer occurs, the yeast must be removed quickly from the production process

2.5. Auxiliary Materials and Brewing Aids

This group comprises all those chemicals that come into contact with the raw materials, the wort, and the beer; they are not essential for the production of beer, and are used for the correction of deficiencies. No general directions exist in the various countries where beer is brewed regarding the use of these materials.

Malting Auxiliaries. Various chemicals may be added to the steeping water. Hydrogen peroxide decreases the sensitivity of barley to water, and reduces the danger of mold formation. Alkaline additives, such as $Ca(OH)_2$ or NaOH, will increase the leaching out of husk tannins.

Gibberellic acid is an effective growth agent; it stimulates enzyme formation and accelerates germination. The amount of growth factor that is to be added to the final steeping water should not exceed 0.05 – 0.1 mg/kg of barley because of the danger of overmodification and additional coloration.

In order to avoid excessive losses of extract during germination, it is possible to add growth inhibitors during the later stage of germination. For this purpose, dilute nitric acid, formaldehyde, or, most commonly, potassium bromate are used.

Sprinkling the green malt towards the end of the germination phase with an aqueous glucose solution will increase the amount of extract to a greater extent than would be expected from the amount of sugar used.

The addition of sulfur dioxide to the air flow during kilning will result in a lighter color and a higher extract yield by lowering the pH value.

Other aids to water treatment are described in Section 2.3.

Brewhouse Auxiliaries. The first concern of the brewer is to eliminate differences in quality of the raw materials which have remained through insufficient modification in the malthouse and which could not be compensated for during mashing. These cytolytic, proteolytic, and amylolytic deficiencies, or the use of an excessively high proportion of adjuncts, will be compensated in the mash by adding enzyme preparations that originate from sources other than malt. The hard, raw aftertaste that frequently occurs in such beers can be reduced by adding mineral acid (HCl, H_2SO_4, H_3PO_4) or concentrated lactic acid to the mash.

During wort boiling, protein-precipitating substances such as formaldehyde, tannin, carrageenan (Irish moss), or protein-stabilizing substances may be added in order to improve the clarification process and stability of the end product. The addition of cross-linked polyvinylpyrrolidone (polyvinylpolypyrrolidone; PVPP) reduces the polyphenol concentration. Synthetic additives based on polyester result in a compact separation of the unpleasant, coarse, and bitter-tasting hot trub.

Numerous advantages can be gained by using a lactic acid culture propagated in the brewery (biologic acidification). The lactic acid bacteria obtained from malt ferment at 45 – 47 °C in 10 – 12 % unhopped first wort, and produce lactic acid (concentration 0.8 – 1.2 %) within 12 – 20 h. The culture is added in the brewhouse during mashing or wort boiling to obtain the desired pH value.

Fermentation and Maturation Aids. Deficiencies in yeast nutrients can be counteracted by the addition of yeast food, which contains amino acids, minerals, vitamins, and zinc salts, to the substrate in order to achieve a vigorous fermentation. Because all enzymes of the malt are denatured during wort boiling, one may wish to add enzymes with a wide activity spectrum, which may additionally enhance the clarification and filtration of the beer in the fermenting room. This will become necessary if the naturally-occurring enzymes achieve an insufficient hydrolysis of malt components with a high molecular mass.

If foam production is impaired by this enzymatic action, which is rather difficult to control, foam stabilizers (alginates, poly(propylene glycol), or polysiloxane) can be added.

After fermentation, bacterial 2-acetolactatedecarboxylase may be added to the fermentation substrate, which will transform diacetyl directly to acetoin (see Section 3.3.2). In this way the maturation rate can be increased considerably.

Antifoaming agents based on silicones have come into use in order to reduce the headspace needed during warm fermentation in tall, cylindrical vessels. A small amount (4 – 8 g/hL) of these agents is sufficient to prevent the formation of a fermentation cover. The foam inhibitor is removed completely by kieselguhr filtration, so that the final foam quality of the beer will not be impaired.

Clarification Aids. Before bottling, the beer is filtered through a filter cake. Proven materials for this purpose are kieselguhr (mud-free, calcined and screened diatomaceous earth) of various particle size distribution, or perlite (ground and calcined glassy rock of volcanic origin.

Activated carbon may be used to correct a mild off-taste; it is usually used in the treatment of rest beers. Shortly before filtration, hydro- and xero-silica gels may be added, which selectively affect the high molecular mass nitrogen fraction, and which also contribute to the build-up of the filter cake.

Stability Improvers. The stability of beer is defined as the ability to preserve its characteristics from bottling to consumption. To ensure an adequate biological stability in zones of moderate climate it is sufficient to clarify the beer through kieselguhr and sheet filters, provided that the beer is delivered to the consumer quickly.

Higher demands can only be met either by the use of insoluble substances which act mechanically or adsorptively, or by pasteurizing the bottled beer (with 12 – 14 pasteurization units), or by hot bottling at 68 – 75 °C. However, heat treatment results in early aging of the beer. Oxygen trapped during filling reacts quickly with the beer. As a result a nonbiological haze may form

sooner or later. This is derived either from tannins or from proteins. Tannins may be removed by adsorption onto polyvinylpolypyrrolidone, or by precipitation with formaldehyde. Haze-forming protein particles may be removed with silica preparations or bentonite. Proteolytic enzymes, such as papain, bromelain, or ficin, decompose high molecular mass proteins to non-hazing components.

During the breakdown of proteins, two characteristics, stability and foam, again run counter to each other. Metal ions accelerate haze formation; they can be complexed with ethylenediaminotetraacetic acid.

During long-term storage beer becomes vulnerable to other dangers including flavor changes, particularly through oxidation, different climatic and mechanical conditions, and effects due to light. The most effective remedy is low-oxygen bottling; if this is not possible, the beer needs to be protected against oxidation by the addition of such antioxidants as ascorbic acid, sulfites, sugar reductones, or by enzymes such as glucose oxidase or catalase. The influence of oxygen during bottling can also be overcome by evacuating the bottles, by pressurizing the bottles with fermentation carbon dioxide, and by allowing fobbing. For additional safety the cleaned beer barrels, kegs, or bottles can be treated with peracetic acid or other products based on hydrogen peroxide, iodine-releasing chemicals, or sulfur dioxide.

3. Production Technology

3.1. Malting

Malting is defined as allowing grain to germinate under well-controlled conditions. The main purposes of malting are the development of enzymes in the grain with simultaneous degradation of high molecular substances in the cell walls (modification), the achievement of a distinctive character by color and aroma compounds, and removal of undesired aroma compounds (i. e. *S*-methylmethionine and dimethyl sulfoxide). High extract yield and low malting loss are economic goals. The schematic procedure of malt production is shown in Figure 1.

Figure 1. Flowsheet of malt production
Additives that are shown in dotted ellipses are not necessary

Figure 2. Steeping

After thorough cleaning with various separators and grading machines, the brewing barley is dried to a moisture content of ca. 12 %, which allows storage without damage to the embryo. If proper drying equipment is not available, cooling of the barley can help prevent its spoilage to a certain extent. Before malting is actually started periodic aeration is necessary to remove the carbon dioxide emanating from the grains, so as to keep the germinating facilities healthy and to maintain germinative ability.

3.1.1. Steeping

Upon addition of water germination of the grain begins. No particular requirements are placed on the steeping water during malting, but it should be of potable quality. In the beginning the water uptake is an osmotic process and depends on water quality and temperature. The grains begin to respire. Respiration is continued during the entire steeping period. At 30 % moisture content the water is taken up via the micropyle (physiological process) and living tissue in the embryo is formed.

Steeping Equipment. The round or rectangular steeping drums with conical bottoms (capacity 2.2 – 2.4 m^3 per ton of barley) must be equipped with a water inlet and outlet, discharge valves, overflow for floaters, a carbon dioxide exhaust vent, and an air inlet for pressure aeration and recirculation. Recirculation pumps and sprayers are optional. The first cleaning is often performed in washing drums.

Steeping Technology. Rapid water uptake and enhanced germination is possible in *pneumatic steeping*, in which wet steeping periods alternate with extended dry steeping periods (the latter during 50 – 80 % of the total period). First of all, steeping provides a definite moisture content appropriate to the physiological characteristics of the barley. During subsequent dry steeping (16 – 24 h) at a moisture content of 30 % the water sensitivity of the barley declines. After further increasing the moisture content to 38 %, a uniform germination of the kernels can be expected within a period of 14 – 20 h. The moisture content is then raised to the final level in the germination box by adequate spraying. An example of the steeping procedure and the necessary handling involved is shown in Figure 2.

When the temperature is raised from one wet steeping period to the next, the temperature of the steeping materials is taken into account. The casting of steeped barley at 18 °C permits the use of a germination procedure with decreasing temperature as shown in Figure 3. Other steeping methods exist based on similar principles: the flushing procedure, the resteeping procedure, and the water-saving spray steeping.

Figure 3. Germination

3.1.2. Germination

Germination is a physiological process during which the embryo develops rootlets and acrospire. During this process, the nutrients stored in the endosperm are partly consumed. The aim of controlled germination is to produce a green malt of a definite composition, but not to allow the development of a new plant.

Germination Conditions. Germination takes place only under appropriate conditions in order to achieve the desired metabolic changes during the time necessary for germination. Parameters are: moisture, temperature, ratio of air to carbon dioxide, and time. Steeping and germination conditions have to be adapted to barley variety, harvest year, water sensitivity, vitality, and furthermore to the protein content and the expected structure of the endosperm matrix. The moisture content must not decrease during the entire germination period. Temperatures favorable to uniform germination range from 14 to 18 °C.

A sufficient supply of air must ensure both normal respiration and removal of carbon dioxide. Germination will manifest itself first in noticeable changes in the appearance of the kernel. After "chitting" (breakthrough of the rootlet), the rootlet divides into a main root and secondary roots (forking). The acrospire also breaks through the aleurone layer and pericarp, and begins to grow under the husk towards the tip of the kernel. During malting the development of the germ buds is desirable only to a certain degree.

Besides these manifestations of growth, chemical transformations occur in the endosperm; stored materials are broken down by enzymes and changed into soluble matter. These are either used as an energy supply, or are built into new tissue in the germ buds. The growth factors which develop during germination cause the formation of a number of enzymes in the scutellum and the aleurone layer.

Enzyme Formation. In addition to certain modifications to the substances of the barley, the main purpose of malting is the induction and increase in hydrolytic enzymes. The most important groups of these are: hemicellulases, proteolytic enzymes, amylases, and phosphatases (see Table 4). Of the cytolytic enzymes, which break down the hemicelluloses to low molecular mass materials, the β-glucanases are considerably more effective than the pentosanases. The degree of cytolysis may be determined empirically by the continuous increase in friability of the endosperm; analytical measurements of the difference between coarse and fine grind extract and the viscosity of the congress wort can be made. Excellent cytolysis is achieved under con-

Table 4. Malt enzymes and their behavior during mashing

Enzyme	CAS registry number	E.C. number	Optimum conditions in mash		Inactivation temperature, °C
			pH	t, °C

Endopeptidases		3.4.4	5.0 – 5.2	50 – 60	70

ditions of high moisture, average temperatures of up to 18 °C, plenty of oxygen, and long germination periods. Before the cell wall is broken down, proteins must be hydrolyzed to a certain extent by proteolytic enzymes. The proteolysis is favored by high moisture content, low temperature, and an optimum germination period; if germination periods are too long, low-molecular protein substances will be consumed for the synthesis of the rootlets and the acrospire. The modification of the proteins can be quantified by the degree of protein hydrolysis (ratio of soluble nitrogen to total nitrogen) and by the total amount of soluble nitrogen.

The protein content of barley decreases somewhat during germination, because the protein-rich rootlets are removed after kilning. The modification of starch by the action of α- and β-amylases occurs to only a moderate degree. The liberation, activation, and formation of the β-amylase, as well as the de-novo formation of α-amylase during the germination process, are both important. α-Amylase can be formed only in the presence of oxygen; its production is favored by a high moisture content during germination, low germination temperatures, and long germination periods.

Germination Technology Practice. The control of the batch is governed by the malting system, and is also determined by the steeping method and by casting. *Germination with increasing temperature* proceeds between 12 and 16 °C; for barley grown in hot, dry climates, the temperature may rise as high as 20 °C towards the end of germination. Slow but even growth, slow enzyme formation, and low enzyme activity characterize the germination process. Green malts are sometimes kept warm during the last 24 h of the germination period in order to attain the desired extent of cytolysis.

During *germination at constant temperature*, respiration and temperature increase are facilitated; this results in a more active metabolism and in strong growth. Maintaining the grain bed at 14 – 15 °C results in most even modification.

With modern steeping and germination equipment it has become common practice to *germinate with decreasing temperature* (Fig. 3).

The relatively warm initial germination phase at a still low moisture content favors quick hydrolysis and high enzyme activity. Enzyme formation is further stimulated by quick cooling of the grain bed and a simultaneous increase in moisture content. Because of the high moisture level, modification occurs satisfactorily in spite of the low temperature. The embryo tries to maintain its original growth rate, and compensates for the impaired living conditions by increased enzyme formation.

In the steep tank and during the early "biological" phase of germination, sufficient oxygenation of the grain bed is necessary for the formation of endo enzymes. In the subsequent "modification phase", a moderate increase of carbon dioxide in the grain bed (up to 4 %) will inhibit too vigorous growth and improve cytolysis. Germination usually takes six days. The different modification properties of the various types of malt can be compensated by varying the germination parameters, especially the moisture content.

Malting Equipment. Floor malting is the oldest and simplest malting method, but it is found only very rarely today. The metabolic activity of the steeped grain, which has been spread on the floor, is controlled by the temperature of the room, by the height of the grain bed, and by turning. The temperature is allowed to rise steadily from the "young pile" through the "growth" and "matting pile" up to the "old pile".

All methods that use aeration (pneumatic systems) are characterized by malting in deep beds. The most important and most difficult task in this type of malting is the constant maintenance of effective cooling of the grain bed by means of an air stream saturated with moisture. Besides supplying oxygen and removing carbon dioxide resulting from respiration, the air stream must also inhibit excessive loss of water during germination. This is not easy to accomplish because the air in the grain bed warms up, and therefore removes moisture. Each pneumatic germination facility consists of aeration installations equipped with temperature control and moisturizing capabilities, ducts for fresh air, exhaust air, and recycled air, and fans. In addition the germination box is fitted with perforated floors, turning and spraying devices, and with discharging equipment.

The various pneumatic malting installations originate from drum or box malting. Drum malting is practically only to be found in the various forms of the Galland drum, or malting box drum. Box malting, with the further development of tower malting or moving grain bed (Wanderhaufen), is almost the only method that has survived. The specific load of a box is 350 – 500 kg/m^2; this corresponds to a depth of the green malt bed of 0.7 – 1.25 m. Among the special malting systems, either the combined germination – kilning system or malting systems where steeping, germination, and kilning occur in one combined installation are used in practice.

3.1.3. Kilning

In order to stop the chemical and biological transformations that take place during germination, the green malt is dried by kilning. This procedure yields a storable product. Another function of kilning is to remove the vegetable-like flavor of the green malt and to impart to the kilned malt a specific aroma and a defined color characteristic for the type of malt required. Finally, the rootlets, which are very much valued as nutritional feed for cattle, are also removed.

The control of drying processes (withering and kilning), together with the quality and modification of the green malt, determine the character and color of the product.

Drying and Kilning. Moist green malt is very sensitive to high temperature. In order to make allowance for this sensitivity, whithering is carried out at high aeration and low temperature. This step decreases the moisture content from the green malt stage to the hygroscopic point (18 – 20 %).

Further drying is accomplished somewhat more slowly, but is still relatively easy to handle up to the point of "breakthrough", at which the temperature above the kiln floor is higher than that of the wet bulb temperature. Breakthrough occurs when the moisture content is ca. 10 %. The subsequent drying procedure at higher temperature and low aeration becomes progressively more difficult, because the internal moisture must be conveyed from the interior of the grain to the surface. The progress of whithering

Figure 4. Drying and kilning of pale malt (single-floor kiln, no air recycling)

Figure 5. Drying and kilning of dark malt (single-floor kiln, air recycling)

and kilning for pale and dark malts in single-floor, high-capacity kilning equipment is shown schematically in Figures 4 and 5.

During the drying of malt the moisture content, volume, weight, and color of the grain change. The dehydration of the green malt lowers the moisture content, which ranges according to the malting technique from 41 to 46 % (pale green malt) and 48 to 50 % (dark green malt) initially, to 3.5 – 4 % for pale malt and 1.5 – 2 % for dark malt. Careful dehydration ensures that the original volume of the green malt remains unaltered.

The chemical and biological changes encompass three stages with relatively different reactions: natural growth, breakdown, and build-up. The formation of aromatic and colored compounds is most important (Maillard reaction). During initial drying most enzyme levels increase and then decrease during kilning, depending on the temperature [8].

Malt Kilns. During malt kilning the grain bed is aerated with drying air. The most primitive, directly heated, single-floor kilns were further developed to the indirectly heated double-floor and triple-floor kilns. Later single-floor, high-capacity kilns were built.

The combined germination – kiln boxes have a specific loading capacity of 420 – 500 kg/m^2. Indirect heating systems, which keep the formation of *N*-nitrosodimethylamines (NDMA) on a low level, require big heating ovens with large heat-exchange surfaces. The use of recircu-

lated air offers various technological and energy-saving advantages. New methods use a thin vertical or horizontal layer and accomplish drying in 8.5 – 9.5 h. The technique exposes practically every grain to the desired kilning temperature without causing any shrinking of the kernels.

After cooling the kilned malt, the rootlets are removed, and the malt is polished. The malt should then be stored before use in the brewhouse for at least four weeks.

Malt Loss. The changes in weight and volume occurring during steeping, germination, and kilning are shown in Table 5.

Table 5. Volume and mass changes during malting

	Moisture content, wt %	Volume, hL	Mass, kg
Malting barley	14	100	100
Steeped barley	41	145	145
Green malt	48	220	147
Kilned malt	3.5	118	79
Stored malt	4.7	120	80

The maltster is mainly concerned with the quality of the malt and the costs of an adequate barley supply [37]. The production costs are also influenced by malt loss. Loss arises during steeping, respiration, and germination, and amounts to 16 – 25 % (average 20 %) and 5 – 12 % (average 8 %) on a dry-weight basis. For quality control standards, see [8] and [23].

Special Malts. *Wheat malt* is produced according to the processes followed for barley malt. *Chit malt* and *short-grown malt* are exposed to short germination periods and have a low degree of modification. *Caramel malt* is made from kiln malt by resteeping and roasting; kiln malt is converted to *black malt* by roasting at a temperature as high as 220 °C and moisturizing. *Scalding malt* is heated to 50 °C at the end of germination and is subsequently kilned. *Acid malt* is enriched with lactic acid bacteria.

3.2. Technology of Wort Production

The high molecular mass substances of the malt and other adjuncts must be solubilized by grinding and mashing. The extract solution is subsequently separated from the solids by lautering. The lautered wort is then boiled with hops, clarified, and cooled. The basic procedures are shown in Figure 6.

Figure 6. Flowsheet of wort preparation
Additives that are shown in dotted ellipses are not necessary

3.2.1. Grinding of the Malt

The manner in which this purely mechanical procedure is carried out is of critical importance both to the chemical and biological transformations during the mashing process and to the composition and yield of the wort. The husks should be crushed as little as possible in order to prevent the undesirable solution of tannins, bitter compounds, and coloring substances, which could have an adverse effect on the taste of the beer. Furthermore, the husks must serve the specific purpose of forming a filter layer during lautering when a lauter tun is used. In contrast, the endosperm requires fine grinding, because it contains the extract components that are to be dissolved.

Nonuniform modification and the resulting differences in hardness of the individual parts of the malt grains cause the products of grinding to differ in size, extract yield, and ease of breakdown. Particles located at the tip of the kernel are undermodified; they are therefore tough and hard, and result in a coarse grind. The portion near the embryo is more friable, and yields a finely ground flour. Grinding also is the basis for wort preparation, because the fineness of the grist determines the grist volume, which in turn determines the volume of the spent grains. During lautering of the wort, the technique of sparging and raking depends on the characteristics of the spent grains (see Section 3.2.3 and Figure 9). The extent of modification and the moisture content of the malt, the mashing procedure, and the lautering equipment determine the degree of grinding. Proper sampling is most important when particle size is assessed by sieving.

Gristing Mills. The grinding of malt is accomplished by using smooth or fluted cast-iron rollers which rotate either at the same or at different speeds relative to each other. The grinding process may be accomplished in one step, or in such a fashion that certain particles are subjected to repeated grinding. Accordingly, the number of rollers ranges from two to six.

The simplest grinding equipment consists of the two-roller mill, which, however, can be used satisfactorily only on malt that is well modified. When four rollers are used, the two upper rollers function as crushers, whereas the lower rollers accomplish the final grinding. Modern types of mills use shaking screens after the first pair of rollers; smaller particles and husks are thus removed, and only the harder coarse particles are ground twice.

Mills with three passages adjust best to the variations in malt quality. To obtain higher capacities, five- and six-roller mills are exclusively employed (Fig. 7). After crushing, the grist is separated into three main fractions: husks, grits, and flour. The husks are directed to the two-husk rollers, where they are freed of the rough particles clinging to them. The coarse grits from the first and second grinding are finally milled in the grits roller pair. Mills with five rollers work similarly. Mills with several milling stages also permit removal of the husks, which are added to the mash at a later stage of mashing. Conditioning of the malt with low-pressure steam or warm water (increasing the water content by 1 – 1.5 %) during multiple-roller milling proved advantageous. In this way, the husks remain elastic and are not destroyed even with thorough grinding.

Figure 7. Six-roller malt mill
a) Feed roll; b) Pair of precrushing rolls; c) Pair of husk rolls; d) Sieve box; e) Pair of grits rolls; f) Sampler

In *wet milling* the malt is steeped and then ground in simple double or quadruple roller mills; in the older systems this is accomplished in one vessel, whereby a moisture level of about 30 % is reached within 10 or 20 min at a water temperature of 50 °C or 30 °C, respectively. In modern systems, moisturizing is accomplished by the use of a worm drive, giving a moisture content of 20 – 22 %.

3.2.2. Mashing

During mashing the solid particles are solubilized by the action of the brewing water and the enzymes formed during malting. The optimum conditions at which these enzymes act on the individual compounds are shown in Table 4.

Starch breakdown is most important during mashing. The solubilization of the starch granules during mixing with water and heating proceeds in various steps. After swelling of the starch kernels, gelatinization of the starch occurs as the enzymatic hydrolysis starts. Starch hydrolysis is allowed to continue until no more α-glucans (dextrins), which give a color with iodine, are present, and the desired attenuation limit is achieved.

Protein hydrolysis is as important as starch hydrolysis, even though smaller amounts are transformed. During mashing, numerous endo- and certain exopeptidases (carboxypeptidases) attack the proteins that were already extensively modified during germination. Depending on the degree of protein modification, the enzyme content of the malt, and the mashing conditions, peptides and amino acids are formed, as well as proteinaceous substances of high molecular mass; the latter are responsible for foam, palate fullness, and nonbiological haze.

The hemicelluloses and gums are hydrolyzed during mashing only after they have been released at temperatures up to 50 °C. The β-glucanases are no longer active above this temperature, so that substances of high molecular mass that are released later during wort preparation by the action of another enzyme cannot be broken down any further. For this reason, uniformity and extent of cytolytic modification is of greatest importance.

The acid phosphatases which occur in the malt hydrolyze the organic phosphates; during this process phosphoric acid is released, which decreases the pH value and increases the buffering capacity of the malt, wort, and beer. Excessive buffering, however, attenuates the drop in pH during fermentation.

Increasing the temperature of the mash and the duration of mashing increases the release of polyphenols and anthocyanidines.

Mashing Parameters. The amount of brewing water used for dissolving the grist and for the chemical and biological transformations constitutes the mash liquor; *spargings* are used to yield the residual extract compounds, which remain in the spent grains after lautering the first wort. The amount of brewing water employed is basically different for all-malt pale and dark beers. For pale beers, a greater volume of mashing-in water is chosen in order to obtain thinner mashes and to speed up the enzymatic processes. The volume of brewing water is about 4 – 5 hL per 100 kg of malt for pale beers, and 3 – 3.5 hL per 100 kg malt for dark beers (mash rates 1 : 4 – 5 and 1 : 3 – 3.5, respectively). The spargings (4 – 5 hL per 100 kg malt) must be added in such a manner that the remaining extract can be yielded as completely and quickly as possible. The last runnings (end of spargings) should always be analyzed for economic usefulness and beer quality (tannins, boiling time).

The intensity of the mashing process is determined by the mashing-in temperature. Temperatures of 35 – 40 °C facilitate solution of the substrate and the enzymes, so that these can be more effective at their optimum temperature. At around 50 °C the breakdown of proteins, gums, and phosphates is increased; thoroughly modified malts can be mashed in even at 62 °C, the optimum temperature for β-amylase.

The dissolution of the ingredients of the brewing materials is already initiated by grinding. Further parameters include the rest periods at different temperatures, the pH value of the mash, and the choice between decoction mashing (boiling parts of the mash) and infusion mashing (no boiling of mash portions).

Mashing Vessels. For mashing-in and for the storage of partial mashes a heatable mash tun, equipped with an agitator, is used. In a similar mash kettle, which is usually smaller, the decoction mashes are heated and boiled. In breweries with a two-vessel brewhouse, the lauter tun is also used as mash tun, and the brewing kettle is also used as mash kettle.

Mashing Procedure. The brewer determines the composition of the various specific beer types by the choice of the mashing procedure. All mashing methods can be derived from the three-mash decoction procedure shown in Figure 8. In two-mash procedures, one of the decoction mashes is eliminated. Single-mash

procedures can be accomplished with infusion before drawing off the decoction mash, with infusion after drawing off the decoction mash, or as kettle-mash procedure (boiling of the total mash, cooling, and saccharification with an enzyme extract that was drawn off at the beginning from the top liquid layer). When the malt is overmodified and enzyme-rich, then a high-temperature two-mash method can be used to advantage. The *infusion methods* require good malt modification. Infusion-mash methods with decreasing temperature have become popular for extremely modified malts and certain beer types such as ale. Mashing-in at 75 °C enhances the activity of α-amylase. During mashing-in the temperature drops to 65 °C. *Grist mashing methods* are intended to treat the different grist fractions on the dual basis of their enzyme content and their convertibility. In the process involving husk separation, the boiling of the husks, and therefore their extensive leaching, is avoided.

Figure 8. Three-mash method
—- Temperature of decoction mash
- - - - Temperature of rest mash

Processing of Adjuncts. Unmalted cereals must be treated thermally before enzymatic breakdown takes place, thus ensuring the conversion of extract-forming components. Malt amylases facilitate the gelatinization of the finely ground adjuncts at low temperature. The grinding of the malt grist must correspond in fineness to the grist part of the adjuncts, and the concentration of the malt mash must be kept very high because a large amount of water is required for optimum adjunct gelatinization (1 : 4 – 5).

Corn is easier to process than rice, because it gelatinizes at lower temperature. Up to 15 % of adjunct can be added to the first decoction mash without any special treatment. If higher proportions of corn are added, a special adjunct mash will be required, in which the ratio of corn to malt is 2 : 1. When almost complete gelatinization and liquefaction have been achieved, the adjunct is boiled and subsequently added to the malt mash.

Some varieties of *rice* will gelatinize completely only at 88 – 90 °C, even if malt is added. After gelatinization, sufficient malt mash held at temperatures of 30 – 40 °C is added; liquefaction then takes place within 10 min at 78 °C. The liquefied material is subsequently boiled and added to the actual malt mash. After that, the mashing procedures described above can take place. The processing of 10 – 15 % unmalted barley will be possible only if the brewing malts are rich in enzymes. Higher proportions of unmalted barley (30 – 40 %) require the addition of enzyme products.

3.2.3. Separation of Wort

After mashing wort is obtained in two steps: (1) lautering of the first wort by filtration, (2) leaching of the extract that remains in the spent grains with hot water (sparging).

Lauter Tun. Commonly used lauter tuns have a total capacity of 8 hL/100 kg and spent grain depths of 30 – 65 cm. They have a perforated false bottom with an open surface representing about 6 – 30 % of the plate area. Rotating, height-adjustable raking machines loosen up the spent grain bed and a spray device delivers the sparging water. During lautering aeration of the wort should be avoided. The mash should remain homogeneous during pumping in, so that a loose, even filter cake can form. Finally, the wort that runs off should be as clear as possible, so that no particles which could disintegrate further during wort boiling (filterability), and only small amounts of the long-chain fatty acids, which destroy foam, can get into the kettle.

Because of the danger of washing out iodine-reactive α-glucans, the sparge water should have

a maximum temperature of 78 °C. In order to avoid channelling, it should be delivered evenly. The ideal performance of a lautering process in a modern lauter tun is shown in Figure 9.

Mash Filter. In place of the lauter tun, several brewers employ mash filters to separate the mash into solids and liquid. The total mash is transferred into a vertically arranged filter press. The frames are covered on both sides with filter cloth made of synthetic material. At the same time, the air must escape quickly when the homogeneous mash is pumped into the chambers. After yielding the first wort, water is pumped in and the filter compartments of the filter press are pressed together with corrugated steel plates. Because very low volumes of sparging water (0.5 hL/100 kg) are necessary, this facility is very suitable for high-gravity brewing.

Characteristic differences between well-automated mash filters and lauter tuns are the following: (1) independence from the quality of the malt and from the proportion of adjunct, (2) quicker lautering of the more highly concentrated first wort, (3) higher yields, and (4) mostly a hazier filtrate.

–■–■– Position raking mashine, mm

Strainmaster. The strainmaster consists of a rectangular vessel, the bottom half of which is conically shaped. In the lower part of the vessel perforated sieve pipes of triangular cross section, which have an open surface area of 10 %, are arranged on top of each other. After pumping off the first wort the sparging water can be pumped in from the top and/or the bottom. A very high first wort concentration of 20 – 23 % is necessary in order to achieve a homogeneous mash. Even with large amounts of sparging water it is not possible to achieve yields as high as those obtained with the lautering systems previously discussed, primarily because the spent grains must be withdrawn while very wet. The major advantages of the strainmaster are its large capacity and rapidity in action – lautering is finished in 70 – 80 min – and its simple, automatic operation.

Continuous Lautering. Equipment that allows continuous wort lautering has not been successfully introduced into breweries because the wort that runs off is very hazy. The most important features of such equipment include a rotary mash filter, a screen-conveyor centrifuge, a belt filter, a vacuum drum filter, the Pablo system with screen centrifuges and separators, and hydrocyclones.

Spent Grain Removal. Spent grain with a moisture content of 75 – 80 % is usually sold to farmers and provides a protein-rich nutrient feed for cattle. Spent grains obtained from a strainmaster must first be demoisturized in a screw press. Spent grains obtained from mash filters have a moisture content of only 60 %. An amount of 100 kg of barley malt yields 120 – 130 kg wet spent grains, whereas wheat malt yields 10 – 15 % less. The dry matter consists of 23 – 28 % protein, 5 – 9.5 % fat, 40 – 47 % nitrogen-free extract materials, 16 – 21 % crude fiber, and 4 – 6 % minerals.

3.2.4. Wort Boiling and Hopping

The wort obtained by lautering (full kettle wort) is boiled; during this time hops are added. The process has several functions, namely: (1) evaporation of excessive water in order to achieve the desired wort concentration (original extract), (2) destruction of enzymes, (3) sterilization of the wort, (4) coagulation of the proteins (the flaky precipitate is called hot break or hot trub), and (5) dissolution and isomerization of the bitter substances of the hops in the wort. In addition, undesirable aroma components are removed, reducing substances are formed, color increases, and the pH value falls slightly.

Wort Boiling. The kettles must have a capacity of 9 hL per 100 kg of malt grist in order to achieve the desired effect through boiling. The most important part of the kettle is its heating mechanism. At first, direct firing was used; this was later changed to oil-heating, and then to steam-jacketed kettles with two-zone heating and a cone-shaped central core.

Today hot water or saturated steam systems (internal or external heating) are frequently used. In conventional kettles the evaporation rate, relative to the final volume, is 8 – 10 % per hour. For technological reasons, the boiling time should not be less than 90 min. The denaturation and subsequent coagulation of proteins will lead to coarse, flaky precipitation products (break) and nonopalescent worts only if the finely divided protein complexes have sufficient chance to come into contact with each other for agglutinization; this is achieved by using small steam bubbles and boiling movement. Boiling by means of various external heating systems provides proper rolling and control of the wort; it results in a high evaporation rate of 10 – 15 % per hour as well as a quick and extensive separation of coagulable nitrogen, so that the boiling time can be shortened to 75 min. Further decrease of the boiling time is not possible because of the length of time required for the isomerization of the bitter substances. However, heating at 108 – 112 °C enables the boiling time to be further reduced to about 60 min.

Continuous Wort Boiling. Completely new possibilities are offered by continuous high-temperature wort boiling systems. At a maximum temperature of 135 °C, the hot holding time required is claimed to be only 150 – 160 s. At higher temperature, heterocyclic nitrogen compounds will increasingly form; these have a very low flavor threshold, and impart a bread-like or cracker-type aroma to beer [30]. After the hot holding period, evaporation proceeds in tandem flash evaporators, and should amount to at least 6 % of the original volume in order to drive off such undesirable aromatic substances as aldehydes, ketones, hydrogen sulfide, and dimethyl sulfide. When these parameters are carefully observed, beers can be produced with high-temperature wort boiling which are of the same quality as those produced under normal boiling conditions [38].

Hopping. The dissolution of the bitter substances is very dependent on pH. At a pH of 5.9, the α-acids are molecularly dispersed, partly as salts (humulates); their solubility is 480 mg/L. However, at a pH of 5.2 only 84 mg/L can be dissolved in a colloidal state. At the normal wort pH of 5.4 – 5.6, the colloidal solution prevails. During wort boiling, up to 40 – 60 % of humulone, cohumulone, and adhumulone isomerize; 5 – 1 % remain unisomerized. A proportion of the bitter substances is oxidized, which also contributes to the bitterness of the beer. The major part of the loss must be attributed to incomplete extraction from the hop cone or hop products, and to precipitation. The remaining α-acids are rendered insoluble as a result of the fall in pH during fermentation, and are expelled in the fermentation cover. The β-acids are not transferred to the wort, but the soft and hard resins are dissolved during boiling, and also impart a certain bitter taste.

The isohumulones are more soluble at low pH values, e.g., about 2000 mg/L at pH 5. Boiling and hot stand times are essential for isomerization. In addition, extraction speed, the age of the hops, the amount of α-acids added, and the wort pH all affect isomerization. If additional contact surfaces are available (as in hop extract powders), the isomerization will occur faster. Separate addition of tannin extracts at the beginning of boiling and of extracts of bitter substances later will result in a higher bitter substance yield, because the bitter substances otherwise adsorb onto the hot trub particles and are lost. In the brewhouse, about 60 % of the bitter substances can be transferred to the wort; only 30 % of the amount originally added remains in the finished beer because of further precipitation during fermentation.

The amount of bitter substance added is expressed in mg α-acid per liter of finished wort, and varies according to the hop product used, and the beer type and variety. Pale beer contains about 65 mg/L, export 80 mg/L, and pilsener 80 – 160 mg/L.

The addition of hops according to variety and timing also influences the bitterness of the beer, but most of all the yield of aroma substances.

Color. Coloring and reducing substances are formed during kilning and mashing. Others develop during boiling of the wort. The numer-

ous amino acids react with reducing sugars to form intermediary products which undergo further transformation to brown melanoidines. The products thus formed possess reducing properties and give acid reactions. Polyphenols also add to the color formation by nonenzymatic oxidation and polymerization. Strong formation of coloring compounds leads to broad and harsh tasting beers which age quickly.

The Finished Wort. The hopped beer wort obtained after boiling is designated as finished wort (cast wort, hot wort). Its extract content and volume needs to be analyzed. The brewhouse yield can be determined from these values; the extract yield is expressed as a percentage of the amount of malt used (range between 78 and 81 %). Table 6 shows the composition of a pale 12 % finished wort.

Table 6. The composition of pale lager wort (12 %) made from barley malt

Carbohydrates (100 %):	
Hexoses	7 – 9 %
Sucrose	3 %
Maltose	43 – 47 %
Maltotriose	11 – 13 %
Lower dextrins	6 – 12 %
Higher dextrins	19 – 24 %
Pentosans	3 – 4 %
Gums	0.2 %
Nitrogen compounds:	
Total nitrogen	950 – 1150 mg/L
High molecular mass nitrogen	200 – 300 mg/L
Low molecular mass nitrogen	550 – 700 mg/L
Free amino nitrogen	200 – 250 mg/L
Bitter substances	25 – 35 EBC bitter units
Polyphenols:	
Total polyphenols	180 – 250 mg/L
Anthocyanidines	70 – 110 mg/L
Minerals	15 – 20 mg/L (80 % inorganic, 20 % organic)
Zinc	0.1 – 0.25 mg/L
pH	5.0 – 5.7
Viscosity (20 °C)	1.7 – 2.0 mPa · s

Wort Concentrates. In some countries it is permitted to manufacture hopped wort concentrates and unhopped malt extracts from wort made by the usual brewing method. Concentration to 70 – 80 % dry matter is achieved either by vacuum evaporation or by lyophilization. These concentrates can be diluted back to the desired extract content in the kettle; they are processed subsequently in the normal manner.

3.2.5. Wort Treatment

Hot Trub Separation. The hot trub contains the nitrogen compounds that coagulate during boiling. These must be removed completely before fermentation, or else the beer will taste wort-like, bitter, and even harsh. The hot trub consists of 40 – 70 % protein, 7 – 15 % bitter substances, 20 – 30 % of other organic compounds, such as polyphenols, and mineral substances. Hot trub yield is between 400 and 800 mg of extract-free dry matter per liter of finished wort. When whole hops are used, the cast wort must first be cleared of spent hops by passing it through a hop back. In the past, the wort was pumped into the flat coolship, where it would cool, and the hot trub and part of the cold trub would sediment. Because of the danger of infection on the large surface of the coolship, the heat loss, and the great expenditure of work, other methods of hot trub separation have been developed.

The *settling tank* (hot wort receiver) permits a good separation of the trub and spent hops, but the amount of sludge collecting on the bottom of the vessel creates problems because 2 – 5 % of the wort is trapped in this sludge. It can, however, be recovered by centrifuging the mixture of trub, spent hops, and wort employing a chamber or plate centrifuge. The wort recovered in this way can be added to the same batch of wort or to the next brew.

The total hot wort is frequently clarified by means of efficient, self-cleaning centrifuges; these, however, will only work reliably if the wort – trub mixture is added homogeneously. This can usually be achieved by means of an intermediate hot wort tank with a stirring mechanism. The most thorough removal of trub and spent hops can be achieved by filtering the hot wort through kieselguhr.

An inexpensive solution is the *whirlpool tank*, where the wort is pumped tangentially into a cylindrical vessel. This creates an even, rotating stream. The solid particles suspended in the rotating liquid will separate due to friction (tea cup effect), migrate to the bottom center, and coalesce to form a cake. It is also possible to achieve this effect in whirlpool kettles, where both boiling and trub separation take place, provided that the bottom of the kettle is appropriately shaped.

Wort Cooling. The wort, which has been freed of hot trub, is cooled to 4 – 7 °C for cold bottom fermentation, to 10 – 15 °C for accelerated bottom fermentation, and to 12 – 18 °C for top fermentation.

Cold Trub Removal. The very fine flaked cold trub appears at temperatures of 70 – 55 °C. It consists of around 50 % protein, combined with 15 – 25 % polyphenols and 20 – 30 % carbohydrates of high molecular mass. At 0 °C about 150 – 300 mg/L of cold trub is formed. Opinions are divided regarding the necessity of cold trub separation. The presence of cold trub can, under certain circumstances, accelerate fermentation because of the presence of long-chain unsaturated fatty acids. The yeast will contain a higher level of impurities and the filterability of beer brewed in this manner may be poor.

A fairly good separation of the cold trub can be obtained in the starting vessel by sedimentation after pitching. Even more effective are: cold sedimentation with or without the addition of kieselguhr, cold centrifugation, and, very elegantly, flotation not only with aeration but the simultaneous addition of pitching yeast. Filtration of the wort removes the cold trub quantitatively; however, a deficiency of minerals and fatty acids could be created by this method. Blending of unfiltered wort can be helpful in this case.

Aeration. The oxygen necessary for yeast propagation (7 – 8 mg/L, corresponding to 80 % saturation of the wort with O_2) is usually introduced in the form of air at the pitching temperature. If pure oxygen is used, it must be added carefully, so that the oxygen level does not exceed 15 mg/L; a higher level is detrimental to the yeast. Optimum aeration can compensate for the disadvantages of an extensive wort clarification. All closed cooling systems require separate aeration of the wort. During normal wort aeration 5 – 15 L of air per hectoliter of wort is needed; flotation requires 40 – 60 L/hL.

Sterile air may be introduced on the cold wort side of the plate cooler with even dispersion by air nozzles or venturi jets, or in the hot wort centrifuge, provided the wort is cooled immediately. A combined hot and cold aeration in the ratio of 1 : 5 also is possible.

3.3. Bottom Fermentation

The flow sheet of Figure 10 describes the basic operations for popular beer varieties from fermentation to finished beer.

Figure 10. Flowsheet of beer fermentation from pitching to final product
Substances that are shown in dotted ellipses are not necessary

3.3.1. Fermentation

The fermentation process is initiated by the addition of 0.5 – 0.7 L of a heavy yeast slurry per hectoliter of wort, corresponding to $15 - 20 \times 10^6$ yeast cells per milliliter of cooled and aerated wort. This procedure is called *pitching*. The batchwise addition of original wort to fermenting green beer is called *doubling*. The main products resulting from the fermentation are ethanol and carbon dioxide. Other reaction products include: higher aliphatic and aromatic alcohols, esters, organic acids, carbonyl compounds, sulfur-containing compounds, and polyhydric alcohols, all of which are important for the properties and quality of the resulting beer (for details on alcoholic fermentation, see → Ethanol). All the compounds formed have different taste and odor thresholds. Their combined contributions make up the flavor or off-flavor of the beer; the amounts produced can be influenced to some degree by brewing technology. Further changes in the wort are caused by the fall in the pH value (see below). The pH drop leads to the precipitation of nitrogen compounds of high molecular mass, of polyphenols, and of bitter agents. The result is a decrease in color and a debittering effect.

Yeast has the ability to adjust its metabolism to aerobic as well as to anaerobic conditions. The yeast doubles or triples its mass during fermentation. For the build-up of cell substance (proteins and enzymes) the yeast needs mostly amino acids, which it either takes from the fermentation substrate or must synthesize by itself. Besides proteins, lipids are also synthesized for yeast propagation because they are important components of the cell wall, and are needed for the uptake of nutrients. For the synthesis of these lipids from acetyl coenzyme A, molecular oxygen is needed; after lautering, wort itself contains only few lipids. Finally, the yeast also requires minerals for the stabilization of its enzyme systems.

Fermentation Byproducts. During the main fermentation, the pH value decreases by one unit because volatile (acetic, formic) and nonvolatile *organic acids* (pyruvic, malic, citric, lactic) are formed. The pH of beer ranges from 4.3 – 4.6. The intensity and speed of acid formation is determined by the buffering action of the wort, the amount of easily assimilated nitrogen, the yeast strain, and the fermentation schedule used. If the pH drops quickly, gums that retard filtration will precipitate, but valuable colloids also are lost. The pH has a direct effect on the flavor and the liveliness (sparkle) of the beer. Short-chain fatty acids are formed during the fatty acid synthesis at the beginning of the main fermentation process: butyric, isovaleric, hexanoic, octanoic, and decanoic acid. Their amounts can be controlled by the wort composition, aeration, yeast strain, and general fermentation conditions. During pressure fermentation, increased levels of these compounds can be expected during maturation. Even in very low concentrations, they cause a yeasty odor and impair head retention.

The higher *aliphatic alcohols* (1-propanol, 2-methyl-1-propanol, 2-methyl-1-butanol, and 3-methyl-1-butanol) and *aromatic alcohols* (especially 2-phenyl-1-ethanol) represent the largest fraction of the compounds responsible for the aroma of the beer; at concentrations which are too high, they will adversely affect taste and quality. Their levels can be controlled to some extent by manipulating the content of free amino nitrogen, wort concentration, pitching rate, yeast strain, pitching temperature, and fermentation temperature.

Because of their low taste threshold values, *esters* strongly influence the organoleptic properties of the beer. Esters are products of enzymatic catalysis and their formation is very closely related to yeast propagation and lipid metabolism. Wort aeration, pitching rate, fermentation temperature, the yeast strain, and the counterpressure during fermentation all have great influence on ester formation. Measures intended to intensify yeast propagation will lower ester concentration.

Sulfur compounds (hydrogen sulfide, sulfur dioxide, dimethyl sulfide, 3-methylthio-1-propanol, and thiols) are not desirable in beer because of their specific odor and taste. Besides efficient trub removal the most important factor in the formation and reduction of these flavor-active substances is the yeast strain.

Glycerol (1300 – 2000 mg/L) is formed as a byproduct during glycolysis; its concentration depends on the amount of fermented sugars.

Aldehydes and ketones are responsible for the aroma of green beer and for the stale flavor. Acetaldehyde formed in the green beer does

not present any technological difficulties. Off-flavors in beer are usually caused by a high level of diacetyl and 2,3-pentanedione; these compounds are responsible for unfavorable, buttery flavor in the beer. The taste threshold of diacetyl depends on beer type, and ranges from 0.10 to 0.12 mg/L; that of 2,3-pentanedione is 0.5 – 0.6 mg/L.

3.3.2. Maturation

The total diacetyl concentration is used to judge the maturity of purged beer, and must be decreased below the flavor threshold by means of brewing technology. The diacetyl precursor 2-acetolactate is called "potential diacetyl", because it transforms into free diacetyl only in the filtered, yeast-free beer, and can then not be broken down any further. In calculating the total diacetyl concentration, 2-acetolactate must be added to the amount of free diacetyl.
